The onset of menarche is largely influenced by genetic factors. However, body fat composition, eating behavior, physical training, chemical pollutants (i.e., endocrine disrupting chemicals), and psychosocial stress can also impact on the timing of menarche (Allison and Hyde, 2011). For example, obesity and stressful life events prior to menarche including parental divorce, absence of a father, maternal mood disorders, presence of a stepfather, or an unrelated man at home are factors associated with earlier menarche. In contrast, excessive dieting, physical training, and thinness are related to a delayed onset (Snowdon and Ziegler, 2007; van den Akker, 2012).

Girls reaching menarche earlier than their peers tend to worry more about menstruation, experience menstruation less positively, experience depression, become more likely victims of peer sexual harassment, and are more likely involved in deviant behavior (Allison and Hyde, 2011). Therefore, further systematic research on the prevention of these adverse outcomes in young girls is necessary.

Menstrual Cycle Disorders

Menstrual cycle disorders are divided in cycle, duration, flow, and pain abnormalities (van den Akker, 2012). Cycle abnormalities include oligomenorrhea (cycle intervals exceeding 35 days), polymenorrhea (cycle intervals of less than 21 days), primary amenorrhea (absence of menarche by the age of 16), and secondary amenorrhea (absence of menstruation for more than 3 months). Normally, menstrual bleeding lasts 3–7 days. Polymenorrhagia (menstrual bleeding exceeding 7 days) and metrorrhagia (bleeding in between menstrual periods) are abnormalities regarding the duration of menstrual bleeding. Flow abnormalities include hypomenorrhea (diminished blood flow) and menorrhagia (very heavy blood flow). Dysmenorrhea is the term used for excessive pelvic pain during menstrual bleeding.

Menstrual cycle disorders are common. Dysmenorrhea is reported in approximately 75–80% of adolescent and in 20–50% of adult women (Harlow and Campbell, 2004; van den Akker, 2012). Oligo- or polymenorrhea have been described by 1.1–42% of women depending on the study and the country of investigation (Harlow and Campbell, 2004).

Menstrual cycle disorders can be caused by structural abnormalities of the endometrium (e.g., tumors), endometrial infections (e.g., chronic endometritis), and by disorders affecting the HPO axis (e.g., renal or thyroid diseases) (Hoffman et al., 2012). Psychosocial stress is also known to impact on the stability of the menstrual cycle and influence the secretion of the HPO axis hormones. For example, a population-based prospective study found that women with high-daily stress levels during one cycle had a twofold increased risk of experiencing dysmenorrhea in the subsequent cycle (Wang et al., 2004). Studies also point toward increased menstrual cycle irregularities after a natural disaster (Li et al., 2011) or a period of war (Hannoun et al., 2007).

Presently, menstrual cycle disorders are treated mainly with painkillers, estrogen therapy, or contraceptive pills. In some severe cases, the uterus is surgically removed (hysterectomy). Few studies have examined the effectiveness of psychotherapeutic interventions. A recent study suggests that cognitive behavioral therapy (CBT) may contribute to the recovery of ovarian function in women with functional hypothalamic amenorrhea (a reversible condition involving absent menstruation with no identifiable organic or anatomical disease) (Michopoulos et al., 2013). Relaxation techniques and physical exercise may alleviate symptoms of dysmenorrhea (Ehlert and Fischbacher, 2012).

Premenstrual Syndrome and Premenstrual Dysphoric Disorder

Premenstrual syndrome (PMS) is characterized by diverse physical and psychological symptoms that occur during the last week of the luteal phase and subside with, or a few days after menstruation (Hoffman et al., 2012). Premenstrual dysphoric disorder (PMDD) – a more severe form of PMS – is defined by the following core psychological symptoms according to the Diagnostic and Statistical Manual of Mental Disorders (DSM-V; American Psychiatric Association, APA, 2013): emotional liability, irritability, depressed mood, and anxiety. At least one additional behavioral (e.g., social withdrawal) or physiological symptom (e.g., breast tenderness) must be present to meet the diagnostic criteria of PMDD. Moreover, symptoms need to have been present during most of the menstrual cycles of the preceding year and involve clinically significant distress, or result in impairment of relationships or work. Symptom-free

periods during the follicular phase are essential to the diagnosis. Therefore, prospective daily symptom ratings are required for a minimum of two cycles to confirm diagnosis.

A recent population-based study found that most women (91%) experienced at least one premenstrual symptom, while 10.3% had PMS, and 3.1% PMDD (Tschudin et al., 2010).

The underlying cause of PMS and PMDD is unclear. Numerous (sometimes contradicting) biological and psychological theories have been proposed. Biological theories focus on the potential influence of estrogen and progesterone and on the neurotransmitters gamma amino butyric acid and serotonin (Hoffman et al., 2012). Genetic factors such as serotonin receptor gene polymorphisms may be involved as well (Dhingra et al., 2007). Psychological models highlight the significance of stress, interpersonal trauma, sociocultural attitudes toward female sexuality, and gender roles in the etiology of PMS/PMDD (APA, 2013). For example, women with PMDD seem more likely to have a history of sexual or physical abuse than women with no PMDD (Girdler et al., 2003). Also, some studies have found marital dissatisfaction to predict PMS/PMDD symptom severity (cf van den Akker, 2012).

Oral contraceptives, selective serotonin reuptake inhibitors, vitamins (e.g., vitamins B_6 and E), minerals (e.g., magnesium, calcium), herbs (e.g., vitex agnus castus), nutrition (e.g., restricted sugar intake), exercise, relaxation, stress management, and psychotherapy are implemented to alleviate PMS/PMDD symptoms (Ehlert and Fischbacher, 2012; Hoffman et al., 2012; van den Akker, 2012). Certain treatment methods are, however, contested (e.g., nutrition, oral contraceptives) and further research, also regarding the etiology of PMS and PMDD, is needed to establish more effective treatments.

Polycystic Ovary Syndrome

Polycystic ovary syndrome (PCOS) is an endocrine disorder of the HPO-axis with heterogeneous symptoms. The chief diagnostic criteria include oligoovulation (infrequent, irregular ovulation) and/or anovulation (no ovulation), hyperandrogenism (excessive androgen secretion), which becomes clinically visible in acne and hirsutism (excessive body and facial hair) and polycystic ovaries identified by ultrasound (Hoffman et al., 2012).

Oligo- or anovulation can lead to menstrual cycle disorders such as oligo- or amenorrhea and consequently women with PCOS can be confronted with fertility problems. Further frequent short-term consequences of PCOS are obesity, abnormal blood lipid concentrations, and glucose intolerance. Long-term consequences include an increased risk of developing type 2 diabetes, high blood pressure, and cardiovascular disease. PCOS is one of the most common endocrine disorders affecting women of reproductive age (Ehlert and Fischbacher, 2012). Prevalence rates range between 6.1 and 19.9% (Yildiz et al., 2012).

The causes of PCOS remain elusive. Genetic factors involved in androgen production and insulin resistance may play a role. The main etiological hypotheses include dysregulation in pulsatile GnRH secretion, insulin resistance, and abnormal ovarian androgen production.

Compared to healthy control women, women with PCOS experience significant psychosocial distress, decreased satisfaction with physical appearance and sexuality (Elsenbruch et al., 2003), higher symptoms of depression and anxiety, and lower degrees of quality-of-life (QoL) (Veltman-Verhulst et al., 2012). Therefore, in addition to medical treatment, women with PCOS may benefit from psychotherapeutic interventions.

Endometriosis

Endometriosis is a frequent, often painful, chronic gynecological condition where endometrial glands and tissues are found outside the uterus (e.g., on the ovaries, the fallopian tubes, the outer surface of the uterus) (Hoffman et al., 2012). These misplaced tissues respond to the hormonal changes of the menstrual cycle. They grow and breakdown monthly, as does the endometrium. However, since the blood cannot flow out, blood-filled cysts develop. This ultimately causes (cyclic or chronic) pelvic pain.

In addition to pelvic pain, symptoms may include dysmenorrhea, pain during sexual intercourse (dyspareunia), urination (dysuria), and defecation, and fatigue and fertility problems (Culley et al., 2013). The severity of symptoms varies largely. Some women with endometriosis are even asymptomatic (Hoffman et al., 2012).

The diagnosis of endometriosis is confirmed by laparoscopy. But, the sites where endometriosis cysts are surgically identified often do not correspond to the sites where pain is felt (Ehlert and Fischbacher, 2012). This makes symptom treatment difficult. It is important to note that, on average, 5–8.9 years can pass from symptom onset to diagnosis. Reasons for such delays can stem both from women not seeking medical help and doctors failing to identify symptoms correctly (Culley et al., 2013). Assessing the prevalence of endometriosis is similarly challenging. Rates lie between 6 and 10% (Giudice and Kao, 2004).

The etiology of endometriosis remains unclear. While dysregulation in estrogen synthesis and metabolism seems to play a key role, it has also been suggested that endometrial tissues are carried away either by retrograde menstruation through the fallopian tubes, or spread via lymphatic or vascular circulation. Furthermore, evidence exists that the immune system may not respond adequately to remove the misplaced endometrial tissue. Heritability, environmental toxins, and anatomical anomalies may contribute to an increased risk of developing endometriosis as well (Giudice and Kao, 2004; Hoffman et al., 2012).

The strong, reoccurring experience of pain can substantially affect psychological well-being and social life. Women with endometriosis frequently report significant impairment in work performance, physical functioning, daily and social activities, reduction in sexual and general QoL, and increased emotional distress, anxiety, and depressive symptoms (Culley et al., 2013). Infertility may additionally cause feelings of inadequacy and negatively affect partner relationship.

The medical, but also psychological treatment depends on symptom specificity and severity. Pain is usually treated with medication (e.g., anti-inflammatory painkillers, oral contraceptives) and in more severe cases with surgery. Less research is available on psychotherapeutic interventions. Endometriosis support groups (including online platforms) have been found to be appreciated by affected women (Culley et al., 2013).

Infertility

The clinical definition of infertility is the inability to become pregnant after 12 months of regular, unprotected intercourse. According to the epidemiological definition, infertility is classified after 2 years (WHO, 2006). The term encompasses the inability to carry a pregnancy to a life birth. Primary infertility is diagnosed if a couple has never conceived before, and secondary infertility if a couple has difficulties conceiving a second time. In many cases, pregnancy is achieved after 2 years also without fertility treatment (Hoffman et al., 2012).

It is estimated that 24% of couples do not conceive within 12 months and 11% within 24 months (Slama et al., 2012).

Causes for infertility are manifold and include behavioral (e.g., advanced age by delaying to have children, obesity), genetic (e.g., genetic disorders), endocrine/hormonal (e.g., hormonal imbalances), and environmental factors (environmental toxins) as well as factors related to diseases (e.g., sexually transmitted diseases) and cancer treatment during child or adulthood (van den Akker, 2012).

Whether psychosocial stress is of etiological significance for infertility, is difficult to assess, as most studies are cross-sectional in design rendering it impossible to disentangle cause and effect, since the diagnosis of infertility itself induces significant distress. Psychosocial stress is, however, known to affect the menstrual cycle as discussed above. Stress has also been associated with an increased risk of spontaneous abortions (involuntary pregnancy loss before the 20th week of pregnancy) and reduced semen quality in men (Nakamura et al., 2008).

The diagnosis of infertility seems to affect women more negatively than men (Hämmerli et al., 2009). Yet, both men and women commonly experience a loss in self-esteem and reduced marital and sexual satisfaction. Active coping and information seeking are associated with less distress, while self-blame, avoidance, and social withdrawal are linked to increased suffering (van den Akker, 2012).

Treatment includes lifestyle changes (e.g., smoking cessation, weight reduction), hormone stimulation, operation of anatomical abnormalities, and assisted reproductive techniques (e.g., insemination, *in vitro* fertilization) (Hoffman et al., 2012). Adoption is an alternative for overcoming involuntary childlessness. Psychological interventions to assist coping with infertility can reduce mental distress and may possibly increase pregnancy rate (De Liz and Strauss, 2005; Hämmerli et al., 2009). However, methodological limitations and conflicting findings call for more systematic research.

Gynecological Disorders Not Related to the Menstrual Cycle

Sexual Dysfunctions

The APA (2013) classifies female sexual dysfunctions according to the following categories: orgasmic disorders, disorders regarding arousal and sexual interest, and pain during intercourse. The problem may either exist from the time of the first sexual experience (lifelong sexual disorder) or develop with time (acquired sexual dysfunction), occur only in specific circumstances (situational) or in all situations (generalized).

Prevalence rates vary depending on the investigated criteria, the applied research methods, the assessed age group or cultural setting. Orgasmic problems have been reported by 10–42% of women, low or no sexual desire by 64%, and pain during intercourse by 15–26% (APA, 2013; Hayes et al., 2006). Interestingly, only a proportion of women experiencing sexual problems seem to feel troubled by it. However, if distress exists, intimate relationship and QoL are likely to be negatively affected (van den Akker, 2012).

Factors important to diagnosis, etiology, and treatment of sexual dysfunctions relate to the partner (e.g., the partner has sexual difficulties too), the relationship (e.g., communication problems), individual vulnerability (e.g., childhood sexual abuse), comorbid mental disorders and stress (e.g., work stress), culture and religion (e.g., tabooing sexual education), and medical factors (e.g., medication) (APA, 2013).

Women most frequently cite relationship conflict as cause of sexual problems (Wylie, 2007). Psychological interventions include sexual education, sensate focus, individual and couple psychotherapy, communication training, relaxation techniques, and biofeedback.

Urinary Incontinence

Urinary incontinence is the involuntary loss of urine (Riss and Kargl, 2011). There are three common forms of incontinence:

1. Stress incontinence is the involuntary loss of urine caused by an increased pressure on the bladder, for example, during coughing, laughing, or sneezing. This is the most common form of incontinence.
2. Urge incontinence is the involuntary loss of urine prior to a sudden urge to urinate, which cannot be controlled.
3. In some cases, stress and urge incontinence are both present and termed mixed urinary incontinence.

Prevalence rates range between 25 and 45% depending on the definition of incontinence and the implemented methods, and increase with age (Buckley et al., 2010). Many women do not seek help out of embarrassment.

Causes for urinary incontinence include hereditary factors, damaged nerves following surgery or trauma, injury of the pelvic muscles following childbirth, or increased intra-abdominal pressure caused by obesity (Hoffman et al., 2012). Incontinence can lead to significant psychological distress and negatively impact women's QoL, daily work, social activities, and sexuality (Riss and Kargl, 2011).

Exercises to strengthen pelvic floor muscles, biofeedback, and scheduled voiding are nonsurgical and nonmedical treatment methods often implemented in psychotherapeutic interventions.

Psychosocial Aspects of Obstetric Health

Pregnancy

Pregnancy (gestation) begins with conception, ends with birth, and spans approximately 38 weeks. But, since the exact time of conception is often difficult to determine, except in pregnancy conceived by *in vitro* fertilization, pregnancy duration is calculated beginning from the first day of the last menstrual cycle – approximately 2 weeks prior to ovulation. This adds up to a total of 40 weeks (Cunningham et al., 2010).

During pregnancy, the female body undergoes massive changes, and the placenta develops into an additional

endocrine organ that produces and secretes hormones in increasing amounts, including progesterone and estrogen (Cunningham et al., 2010). Progesterone and estrogen exert negative feedback on FSH and LH, and thus egg maturation in the ovaries is suppressed during pregnancy.

The placenta also synthesizes CRH and adrenocorticotropin in increasing amounts. This causes an upregulation of the maternal HPA axis and an increase in maternal cortisol levels. Cortisol can cross the placenta and reach the fetus. To a certain extent it furthers fetal lung and brain development (La Marca-Ghaemmaghami and Ehlert, in press). Fetal overexposure to maternal cortisol, however, has been associated with adverse pregnancy outcome including preterm birth and low birth weight. It is further assumed that cortisol excess *in utero* may have programming effects on fetal organ development rendering the child vulnerable to disease in later life, including hypertension, type 2 diabetes, and cardiovascular disease (Harris and Seckl, 2011).

The underlying biological mechanisms of prenatal stress are just beginning to be understood. Findings suggest that when a certain level of placental CRH is attained, processes are triggered that ultimately lead to birth (McLean and Smith, 1999). Excessive maternal stress may prematurely increase placental CRH concentrations via maternal cortisol which unlike hypothalamic CRH stimulates placental CRH production.

A further mechanism by which stress may affect the fetus involves a placental enzyme named 11β-hydroxysteroid dehydrogenase type 2 (11β-HDS2). This enzyme controls the amount of maternal cortisol crossing the placenta by inactivating cortisol to cortisone. It is assumed that acute stress induces an upregulation of 11β-HDS2 activity, whereas chronic stress impairs its function exposing the fetus to increased cortisol concentrations (Welberg et al., 2005).

Although pregnancy is usually a happy event, the many physiological, hormonal, psychological, social, and socioeconomic changes that are brought on by pregnancy can be sufficiently challenging to provoke psychological maladjustment. Some findings even suggest that mental health problems are higher during pregnancy than postpartum (van den Akker, 2012). The prevalence rates for prenatal depression range between 7 and 20% and are estimated at 6.6% for prenatal anxiety disorders. Anxiety symptoms have been found in 54% of pregnant women and depressive symptoms in 37.1% (Lee et al., 2007). Psychological problems during pregnancy often remain unidentified, undiagnosed, and untreated, and pose a risk to maternal mental health after birth (Ghaemmaghami and Ehlert, 2012).

Pregnancy per se does not induce psychological problems and women's experiences of pregnancy vary substantially (Stanton et al., 2002). Factors associated with increased prenatal stress and psychological maladjustment include socioeconomic inequalities, poverty, racism, unwanted or adolescent pregnancy, lack of a partner and social support in general, problematic in-law relationship, single motherhood, first pregnancy, previous pregnancy loss, pregnancy complications, pregnancy by rape, domestic abuse, critical life events, chronic stress, and pregnancy-specific anxiety (Dunkel Schetter and Glynn, 2011; WHO, 2008).

Systematic psychological intervention studies for the alleviation of stress and the treatment of depression and anxiety during pregnancy are rare. A few have found a beneficial effect of psychotherapy and relaxation techniques on psychological symptoms and levels of stress hormones (Dennis et al., 2007; La Marca-Ghaemmaghami and Ehlert, in press). However, with increased knowledge about how prenatal psychological problems can impact on postpartum maternal well-being and child development, more studies in the field of prevention and therapy are warranted.

The Postpartum Period

Despite the joy the birth of a child brings, new responsibilities and demands of motherhood, such as breast feeding and lack of sleep can cause substantial psychological strain and, under certain circumstances, raise the vulnerability for psychological maladjustment. Possible mental health problems during the postpartum period (period following childbirth) include: (1) postpartum blues, also known as maternity or baby blues, which is characterized by increased negative emotional reactivity in the first days following childbirth (prevalence: 55.2%), (2) maternal postpartum depression, which is a major depression following childbirth (prevalence: 6.5–22%), (3) postpartum post-traumatic stress disorder (PTSD), which can develop in response to a traumatic birth experience (prevalence: 6–14%, subsyndromal symptoms in 28%), (4) postpartum obsessive-compulsive disorder (OCD), which is characterized by maternal obsessive-compulsive thoughts of harming the child with or without intention (prevalence: 2.7–3.9%), (5) peri- or postnatal panic disorder with excessive fear concerning infant well-being (prevalence: 1.3–2%), and (6) postpartum psychosis, which is a sudden psychotic or bipolar depressive disorder with an increased risk for suicide or infanticide (prevalence: 0.003%) (van den Akker, 2012; Cunningham et al., 2010; Reck et al., 2009; Zaers et al., 2008). Fathers can develop postpartum depression as well (prevalence: 10.4%) (Paulson and Bazemore, 2010).

Besides postpartum psychosis, a general increased risk of maternal suicide during the perinatal period has also been reported in several studies. In fact, in the United Kingdom and Australia maternal suicide is the leading cause of death during the perinatal period (WHO, 2008).

The etiology of postpartum mental disorders is poorly understood, and the hormonal alterations after birth explain symptoms only partially. A prior history of mental health problems, medical complications during pregnancy or birth (e.g., preterm birth), low socioeconomic status, financial problems, relationship dissatisfaction, low social support, increased stress, and a history of sexual abuse can increase the risk of developing mental problems postpartum (van den Akker, 2012; Cunningham et al., 2010).

Receiving psychological treatment as soon as possible is crucial, because both maternal and paternal postpartum disorders can significantly affect infant emotional and behavioral development. In some cases, antidepressants are required, although psychotherapeutic treatment should receive preference.

Psychosocial Aspect of Menopause

Menopause marks the end of female reproductivity and is defined as the permanent cessation of menstruation. It is

determined retrospectively, after 12 months of absent periods and occurs internationally at an average age of 49.2 years (Drobnjak, 2012; Thomas et al., 2001). Menopause is embedded within a phase of hormonal changes associated with natural aging in women. This phase is termed menopausal transition or perimenopause. It begins at an average age of 47 years and lasts between 4 and 7 years (Hoffman et al., 2012). The phase following menopause is termed postmenopause.

The end of menstruation is caused by a gradual decline in ovarian function due to the age-related decrease in follicle numbers. Ultimately, the ovaries stop producing estrogen and progesterone, and the negative feedback that these hormones usually exert on the hypothalamus and pituitary is lost. Hence, secretion of GnRH from the hypothalamus and FSH and LH from the pituitary increases. The equilibrium of the HPO axis is temporarily disturbed until the body readjusts.

The physiological changes associated with menopause can induce diverse symptoms including hot flashes, fatigue and sleep disruptions, bone mass loss, cardiovascular changes and an increased risk for cardiovascular disease, weight gain, urinary incontinence, sexual problems, particularly pain during intercourse due to vaginal dryness, and psychological symptoms such as poor concentration, forgetfulness, and in some cases depressed mood (Drobnjak, 2012; Hoffman et al., 2012).

For up to 85% of menopausal women these symptoms are considered rather unpleasant, and QoL is reduced for more than 50% (van den Akker, 2012). Epidemiological studies indicate an increased risk of developing depression during menopausal transition by about 30% as compared to premenopause. This risk has been found to be five times higher in women with a prior history of depression (Freeman, 2010). It is nevertheless important to emphasize that menopause per se does not cause depression and that most women experience the years of menopausal transition positively.

Although hormonal changes in estrogen, FSH, and LH concentrations (e.g., increased FSH and LH and increased variability in estrogen, FSH, and LH concentrations during menopausal transition) have been suggested to affect women's mood, this hypothesis has not been clearly established (Freeman, 2010). The elevated risk of developing depression during menopause seems to be multifactorial and likely to be influenced by psychosocial and behavioral aspects as well. These may include factors such as the appraisal of and attitude toward menopause, aging, and the end of reproductivity, the influence of cultural values, critical life events, financial problems, low social support, single relationship status, lower educational status, increased BMI, sleep problems, and smoking (van den Akker, 2012; Freeman, 2010).

Treatment of menopausal symptoms ranges from lifestyle changes (e.g., physical activity) and antidepressants to hormone replacement therapy. The latter has been associated with considerable side effects including breast cancer and poor compliance. A few studies examined the effect of psychological interventions and CBT, and found symptom alleviations and improved coping (van den Akker, 2012).

Abstract

The philosopher and sociologist Jürgen Habermas (1929–), remains deeply influenced by his teenage experiences under and immediately after the Nazi regime. As he has said, the theme of democracy and rational communication runs like a red thread through his work. His critical theory of society is in many ways a continuation of the earlier critical theory developed in the Frankfurt Institut für Sozialforschung.

Jürgen Habermas, born in 1929 and brought up in the small northwest German town of Gummersbach, remains deeply influenced by his teenage experiences under and immediately after the Nazi regime. As he has said, the theme of democracy and communication runs like a red thread through his work. His critical theory of society is in many ways a continuation of the earlier critical theory developed in the Frankfurt Institut für Sozialforschung until 1933, then in exile and again from 1950 in Frankfurt.

Unlike the experience of these 'permanent exiles' (Jay, 1985), Habermas's life has been relatively tranquil. He studied in Göttingen, Zürich, and Bonn, where he was drawn into the first of many interventions as a public intellectual by the philosopher Martin Heidegger's republication without comment, in 1953, of an article of 1935, which included a complimentary reference to the Nazi movement. Invited by Theodor W. Adorno to work as his assistant at the Institut für Sozialforschung, he participated in a survey of student political opinion and began work on his habilitation thesis on the public sphere. Driven out of the Institute by Max Horkheimer, for whom he was too radical, he completed this work at Marburg with the Marxist political scientist Wolfgang Abendroth. After teaching for a time at Heidelberg, he took up Horkheimer's chair in philosophy and sociology at Frankfurt in 1964. An active supporter but increasingly severe critic of the student movement of the late 1960s, he left Frankfurt in 1971 for a 10-year period as codirector of a research institute in Starnberg, where he completed his *Theory of Communicative Action* (1981). After 12 years back in Frankfurt, he retired in 1994 to Starnberg, where he has continued an astonishingly productive program of writing and worldwide lecturing.

Two of the main ways in which Habermas's work differs from the earlier critical theory of Adorno, Horkheimer, and Herbert Marcuse are a more distanced attitude to Marxism and a closer engagement with contemporary sociological research. Philosophy, in Habermas's conception, serves as a 'placeholder and interpreter' for the social sciences: it can raise issues for further analysis by the social sciences and it can generalize and reflect on their results (Habermas, [1981]1983).

Methodology: Reconstructive Science

Habermas's methodological critique of positivism in social science went along with his criticism of technocratic politics in the early 1960s, initially in his contribution to the 'positivism dispute' (Adorno [1969]1976), and then in major works of the late 1960s. Here, Habermas developed an approach that rejected positivism for its reduction of epistemology to methodology and its failure to appreciate the differences between the natural and social sciences. At the same time, he criticized what he called the 'hermeneutic claim to universality' and argued that understanding (Verstehen) needed to be complemented by causal explanation in a model of 'emancipatory' social science exemplified by Freudian psychoanalysis and the (originally Marxist) critique of ideology. Theories of this kind combined the two methods in an attempt to identify causal obstacles to the understanding of personal and social problems, which a purely interpretive approach could not capture. However, as he wrote later in a new preface to this work, the problem of Verstehen remains important because mere observation does not give access to a 'symbolically structured reality' and because "a participant's understanding is not as easy to monitor as an observer's perception" (Habermas, 1982a: 549).

Habermas's critique of positivism went along with a cautious appropriation of elements of the Marxist tradition – the theory of ideology in particular. Critical theory's response to what Habermas, following Horkheimer, calls 'traditional theory' parallels Marx's critique of idealist philosophy (Habermas, [1968] 1986: 212).

In the 1970s, Habermas came to feel that this epistemological approach, a model of knowledge grounded in 'cognitive interests' (in prediction and control, as in positivist conceptions of natural science, in understanding, as in hermeneutics,

and in 'emancipation' from unnecessary and unwanted constraints) was too rigid to capture the diversity of social science. He turned instead to seek an alternative foundation for critical social science in an analysis of human communication and, more broadly, 'communicative action.' When we make statements about states of affairs in the world, about our feelings or about what we consider right, we commit ourselves to offering grounds for these utterances to someone who might disagree. In this sense, our speech acts, if they are more than just orders or attempts to manipulate others, are oriented toward possible agreement. Communicative action in this sense is distinguished from, and prior to, 'strategic action,' as conceptualized in economic and rational choice approaches, 'normatively regulated action,' as theorized by Talcott Parsons and other functionalist sociologists, and 'dramaturgical action' as in Erving Goffman's 'presentation of self in everyday life.' For Habermas, the teleological and strategic, the normative and the dramaturgical model are 'one sided' or 'simplistic': "Only the communicative model of action presupposes language as a medium of uncurtailed communication …" (Habermas, 1987a: 142).

> The concept of *communicative action* refers to the interaction of at least two subjects capable of speech and action who establish interpersonal relations (whether by verbal or by extra-verbal means). The actors seek to reach an understanding about the action situation and their plans of action in order to coordinate their actions by way of agreement.
> (Habermas, 1987a: 86)

The theory of communicative action is not 'a continuation of the theory of knowledge by other means' (Habermas, 1987a: xxxix) but a 'reconstructive science,' which, like linguistics, explicates the rules and principle underlying our everyday speech and action (Habermas, 1987a: 18–19). As he said in an interview,

> I never say that people *want* to act communicatively, but that they *have to*. When parents bring up their children, when the living appropriate the transmitted wisdom of preceding generations, when individuals and groups cooperate, […] they all have to act communicatively. There are elementary social functions that can only be satisfied by means of communicative action.
> (Habermas, 1994: 111)

Habermas presented this model in his major work in 1981, through a detailed discussion of the history of social thought and methodology and a reflection on the history of Western modernity. Very briefly, the Enlightenment meant rational and critical reflection on tradition, but societal rationalization also brought with it the decoupling of economic and administrative systems from rational scrutiny, with markets and state bureaucracies following their own logics. Habermas had addressed these questions in his early book, *Structural Transformation of the Public Sphere* (1962), which examined the emergence in late seventeenth- and eighteenth-century Europe of a critical public, reading newspapers and discussing current issues in coffee houses and salons. This was based on "post-traditional legal and moral representations" (Habermas, 1987b: 166).

Max Weber continually points to the paradoxes of rationalization, such as the irrationality of a work ethic pursued to extremes, whereas Habermas poses the more precise question of an 'imbalanced' rationalization process, in which "the capitalist economy and modern administration expand at the expense of other domains of life that are structurally disposed to moral-practical and expressive forms of rationality and squeeze them into forms of economic or administrative rationality" (Habermas, 1987b: 183).

Here, Habermas refers to Marx and more precisely to Georg Lukács' concept of reification (Verdinglichung), which blends Weber's rationalization with Marx's concept of alienation or estrangement. The theoretical framework, then, is that of Western Marxism, in particular the early critical theory of Horkheimer, Marcuse, Adorno, and others. But where Max Weber, as he sees it, conceives rationalization in cognitive and individualistic terms and Adorno and Horkheimer lapse into an abstract, pessimistic, and ultimately unpromising critique of instrumental reason, Habermas grounds his critique of capitalism in a theory of communication. The specific pathologies of modernity are above all the reduction of the possibilities of communicative action through the 'colonization of the lifeworld.'

The counterfactual question then became whether we could have had the first form of rationalization without the second; the practical question whether we can reestablish democratic control over these processes. He ended the book with a statement of what he saw as the task of a critical theory of society: "explaining those pathologies of modernity that other approaches pass right by for methodological reasons" (Habermas, 1987b: 378). Here he reformulated some of his earlier analyses of crisis tendencies in advanced capitalist societies. There he had argued that crises of capitalist reproduction were increasingly displaced into rationality crises in state policy, legitimation crises, and crises of individual motivation. He restates this theme in the *Theory of Communicative Action*: that the "new conflicts" are located less "in domains of material reproduction" and rather "in domains of cultural reproduction, social integration and socialization"(Habermas, 1987b: 349).

The basic categories of Habermas's theory are, then, those of a broadly conceived sociological theory of action, which, however, also incorporates social historical and system-theoretical, as well as structuralist elements. Although he borrows some concepts from Talcott Parsons (Holmwood, 2009) and often mentions Niklas Luhmann, his conception is closer to those of Pierre Bourdieu and Anthony Giddens (Outhwaite, 2015).

What Habermas (1987b: 553) stresses is that system theories and theories of action 'isolate and overgeneralize' aspects of modernity (system and lifeworld, respectively). When, here and elsewhere, he emphasizes the role of language, he does not intend to reduce "social *action* to the interpretive accomplishments of participants in communication … assimilating action to speech, interaction to conversation" (Habermas, 1987a: 143). This is rather the way in which action is 'coordinated.'

The one-sidedness of the other action models can also be illustrated sociologically. I can act strategically but do not, I think, always do so; I can act thoroughly dramaturgically, for

example, by 'power dressing,' or not bother; I can orient myself to norms or ignore them, like tourists who behave as they would at home. The reference above to mechanisms of action coordination (Habermas, 1987a: 143) shows that Habermas is going beyond a narrowly conceived theory of action. An alternative form of action coordination is through markets and bureaucratic power.

Social Change: Rationalization, Increased Complexity, and the Colonization of the Lifeworld

Habermas borrows the concept of the lifeworld from phenomenological philosophy (Husserl) and its sociological adaptation by Alfred Schütz. But for Habermas it has a rather different meaning: the realm of informal social interaction, the informal coordination of action by language and, more broadly, by communicative (and also strategic) action. Relations between friends and family members are usually regulated informally rather than by monetary or legal transactions.

Habermas welcomes the explicit formulation and reflexive examination of norms in modernity, and sees the coordination of action through money and markets as a necessary increase in complexity that goes along with societal development. These formal media of nonlinguistic interaction, (I can buy a paper from a machine as well as from a friendly newsagent) only become problematic for Habermas when they intrude damagingly into the normative organization of the lifeworld, leading individuals to think of their whole lives in categories appropriate to the work process (Iser, 2009: 329).

Habermas has from time to time distanced himself from this model of colonization, but he would probably still endorse the principle he formulated in relation to the beginnings of the process of social differentiation: money and power "need to be institutionally and motivationally anchored in the lifeworld" (Habermas, [1981]1987b: 342). In 1981, the concept of juridification ('Verrechtlichung') had pejorative connotations, whereas with the development of his theory of law in the following decade it appears in a more positive (or, as some have suggested, uncritical) light.

The Democratic Constitutional State

In its developed form, Habermas's critical theory of modern society is no longer framed as a philosophy of history, as in the early 1960s (*Theory and Practice*), or in epistemological terms (*Knowledge and Human Interests*), but on the basis of a reconstruction of the implicit rules of communicative action. This yields not only a social theory but also a 'discourse ethic' or, more precisely, a discursive foundation for morality, in which to say something is right is to say that all those affected could come to a rational agreement about its rightness. This in turn leads to a theory of law and democracy.

Discourse ethics, based on the same reconstructive principles of universal pragmatics as the theory of communicative action, is also reconstructive in that, rather than prescribing a basic moral principle in abstract terms, it derives it from our daily communicative behavior. "The universalization principle can be understood […] as a reconstruction of the everyday intuitions underlying the impartial judgement of moral conflicts of action" (Habermas, 1990: 127). It "stands or falls with two assumptions: (a) that normative claims to validity have cognitive meaning and can be treated *like* claims to truth and (b) that the justification of norms and commands requires that a real discourse be carried out and therefore cannot occur in a strictly monological form, i.e. in the form of a hypothetical process of argumentation occurring in the individual mind" (Habermas, 1990: 68). As Thomas McCarthy (1978: 326) put it, "The emphasis shifts from what each can will without contradiction to be a universal law to what all can will in agreement to be a universal norm."

Habermas's moral principle, like the Kantian principle to which McCarthy alluded, is a formal one: the content comes from human communities. The basis for Habermas is what he calls the discourse principle: "Just those action norms are valid to which all possibly affected persons could agree as participants in rational discourses" (Habermas, 1996: 107). Habermas draws a distinction between fundamental moral issues and ethical ones, where local conventions play a bigger part. (This is of course somewhat problematic: abortion, for example, may be treated as a moral issue, but abortion legislation was notably more liberal in communist East Germany, where almost all Christians were Protestants, than in West Germany, with a Catholic majority.)

The discourse principle can also form the basis for legal norms, where again ethical and pragmatic considerations play a role. This yields, for Habermas, a very close connection between law and democracy: under modern conditions, legal principles can only be justified by democratic procedures. The last sentence of the 'Tanner Lectures' of 1986, in which Habermas first presented this theory, reads: "No autonomous law without the realization of democracy" (Habermas, 1986: 279). In *Between Facts and Norms*, Habermas (1996: xlii) repeats this claim, that "in a sphere of fully secularized politics the Rechtsstaat cannot be achieved and preserved without radical democracy." This aspect of Habermas's thought might seem a departure from social science toward normative questions of moral and political philosophy, but Habermas ([1992]1996: xl; 5-8) would resist this suggestion, stressing the parallels between legal and social theory.

As he often does, Habermas presents his conception of democracy as a synthesis between two conflicting alternatives: Discourse theory's 'deliberative' model of democracy incorporates elements both of the liberal conception of politics as the mediation of private interests and of the republican conception of a self-organizing ethical community (Habermas, [1992] 1996: 296). Solidarity, a very important concept for Habermas (Dews, 1992), is a driving force of this model of democracy and "… can also hold its own, in the medium of law, against the two other mechanisms of social integration: money and administrative power" (Habermas, [1992]1996: 299).

The critical response to *Between Facts and Norms* has focused on three issues. First, his optimistic conception of law, which has particularly disappointed readers associated with 'critical legal studies.' Second, and relatedly, his scaled-down expectations about the prospects for socialism. In his reflections on the anticommunist revolutions of 1989, Habermas, who had always condemned the state socialist dictatorships, declared (Habermas, [1990]1992) that he no longer saw a state-

controlled economy as realistic and that he now understood socialism as 'radical democracy' (Scheuerman, 1999).

The third question concerns the way Habermas framed his account of the constitutional state in relation to the national state and failed to address the implications of globalization, which had become a major focus of attention since early in the 1990s. David Held, Mary Kaldor, and others were already developing conceptions of 'cosmopolitan democracy,' which Habermas was quick to embrace.

In a postscript to his interview volume *The Past as Future* (Habermas, [1991]1994), he referred to Paul Kennedy's criticism of the national state: "For some problems, it is too large to operate effectively; for others, it is too small" (Kennedy, 1993: 131).

By 1996, he was asking 'Has the nation-state a future?'; and in *The Postnational Constellation*, he poses the question (Habermas, 2001: 90) "whether political communities can form a *collective identity* beyond national borders, and thus whether they can meet the legitimacy conditions for a postnational democracy."

Since then, Habermas has been centrally concerned with the prospects of the European Union, speaking eloquently for federalism, though now with increasing pessimism. "Executive federalism" threatens to develop into "intergovernmental rule by the European Council," in which "the first transnational democracy would be transformed into an arrangement for exercising a kind of post-democratic, bureaucratic rule. The alternative is to continue the democratic juridification [Verrechtlichung] of the European Union in a consistent way" (Habermas, [2011]2012: 52–53).

Habermas's conception of 'postnational' democracy includes a recognition of the persistence of 'still nationally shaped life projects'; the post-, preface indicates persistence as well as transformation. In the EU context, this means that people "must learn to distinguish between the role of a member of a 'European people' and that of a 'citizen of the Union'" (Habermas, [2011]2012: 29), with this idea of a double mandate as a German or Briton and as a European serving as a guide to further constitutional innovations.

Another area of Habermas's recent work is shaped around what he admits is the controversial concept of a postsecular society (Habermas, 2001a; 2001b; [2005]2008; Habermas and Ratzinger, 2005). Habermas does not mean by this that the Enlightenment critique of religion has run out of steam and that religion is back after all. It is rather that modernization has led to a secularized and ideologically plural society in which religions have to 'reflexively' confront other belief systems (Habermas, 2001a: 176f.). Since 2001, Habermas has addressed questions of religious fundamentalism and returned to the theme of multiculturalism that he had analyzed in *The Inclusion of the Other* (1996), notably in essays on religious tolerance in *Between Naturalism and Religion*; see also Joas, 2005; Anderson, 2007. (His discussion with Cardinal Ratzinger attracted additional publicity when Ratzinger became Pope; Habermas has stressed that he has not himself become religious.)

The term naturalism refers to a further theme of Habermas's recent work (Habermas, 2003): the implications of new biomedical techniques (genetic engineering, cloning, etc.) for what he calls 'liberal eugenics' and more broadly for our ideas of human identity – issues that had of course also attracted the attention of religious leaders (Habermas (2001b: 9; 2005: 7)).

All this raises again the question whether Habermas should be seen more as a philosopher than a sociologist, as his old friend Ralf Dahrendorf suggested. It is probably more useful to see him mediating between philosophy and sociology, just as, in philosophical terms, he moves between Kantian and Hegelian impulses, notably in his ethical philosophy, and in political terms between liberalism, especially in relation to human rights, and socialism.

Critiques and Continuations

One of the most striking features of Habermas's work is his engagement with a vast range of specialized fields, so it is notable that he had something of a blind spot in relation to postmodern theory and to major contemporary figures such as Michel Foucault, Jean-François Lyotard, and Jacques Derrida; also to Pierre Bourdieu and perhaps even Niklas Luhmann, despite his substantial exchange with him published in 1971. Others have pointed to affinities between these approaches and Habermas's.

A more serious line of criticism suggests that Habermas's theories are structurally blind to certain perspectives. Feminist critics, for example (Nancy Fraser, Seyla Benhabib, Amy Allen, Diana Coole), have pointed to patriarchal assumptions behind his models of the public sphere and politics, and to the fact that modernity may even have reinforced the exploitation and exclusion of women.

In other areas of social theory, many critics have suggested that he takes too much from Talcott Parsons, notably his system theory and his stress on norms. Anthony Giddens pointed to this: "it is an error to suppose that communicative action can be examined solely on the level of norms" (Giddens, 1982a: 157–158; see also Giddens, 1982b). Hans Joas (1991) referred more broadly to an 'unhappy marriage' of hermeneutics and functionalism and Thomas McCarthy (1991) to the 'seducements of system theory.' More recently, John Holmwood has criticized his acceptance of Parsons' assumption "that a general theoretical framework is a necessary precondition for social enquiry and that it can be grounded in terms of a generalized problem of social order" (Holmwood, 2009: 70).

Other critics argue that Habermas has abandoned too much of Marx, again ascribing too much independence to moral and legal principles that Marx saw as ideological. What is clear is that from an early stage in his work, Habermas, partly influenced by Max Weber and early critical theory and partly by system theory, developed an analysis of societal modernization which was quite far from orthodox Marxism (Habermas, 1971: 98).

On the other hand, Habermas stressed in an interview in 1984 that

> … from the outset my theoretical interests have been consistently determined by those philosophical and socio-theoretical problems which arise out of the movement of thought from Kant through to Marx. My intentions were given their stamp by Western Marxism in the mid-fifties, through a coming-to-terms with Lukács, Korsch and Bloch, Sartre and Merleau-Ponty, and of course with

Horkheimer, Adorno and Marcuse. Everything else which I have made my own has only acquired its significance in connection with the project of a renewal of the theory of society grounded in this tradition.

Habermas is not offering an alternative to such a broad theory as historical materialism, but rather a theoretical framework that can be applied (as he does himself in outline) to historical processes such as the development of Western modernity. In other words, the theory of communicative action can only be part of a critical theory of society. What Habermas formulates is a logic of development from processes of mutual understanding in the lifeworld all the way to the democratic constitutional state, but the forms of these developments and countermovements require further exploration.

Habermas's concept of modernity is of course contentious, as Anthony Giddens (1982b: 335) noted in an early review. Since then, postcolonial critics have fundamentally problematized the concept of modernity (Bhambra, 2007; G.R. et al., 2010; see also Wagner, 2012). Habermas, like Max Weber, may seem too fixated on the 'European miracle,' but Klaus Eder (2009: 66–68) has defended his evolutionary conception of modernity as a process of communicative sociation and a universalistic culture that happened to emerge at particular times and places. Postcolonial critics might still want to suggest that Habermas and others overemphasize the endogenous character of European and North American modernity.

A Habermasian approach has been carried forward by what can be called a third generation of critical theorists, notably Axel Honneth and Seyla Benhabib. Honneth, who took up Habermas' chair in Frankfurt on his retirement in 1996 and followed Helmut Dubiel as Director of the Institute for Social Research, has developed a theory focusing on concrete struggles for recognition driven not just by exploitation but by broader experiences of 'disrespect' and based on "empirically effective forms of morality to which critical theory can connect" (Honneth, 2000: 110). This feeds into conceptions of social pathology and a revival of the notion of 'diagnoses of the times.'

Honneth is in a sense returning to an earlier focus of critical theory on social movements. In a similar way, Seyla Benhabib, Nancy Fraser, and others in the United States have developed the links between critical theory and feminist theory. Benhabib (2004, 2006) has more recently turned in particular to questions of migration, ethnicity, and citizenship in Europe, arguing that structures developed to address cultural pluralism and minority rights are, "quite compatible with a universalist deliberative democracy model" (Benhabib, 2002:19). The development of theories of deliberative democracy by John Dryzek and others is a further important continuation of Habermasian theory.

Habit: History of the Concept

Abstract

This article examines aspects of the history of the concept of habit in Western social thought. As an expression, the concept of habit has generally referred to a disposition to act as one has previously acted, whether in regard to simple behaviors, more complex forms of conduct, or broader characterological tendencies (habitus). Among social thinkers who have used the concept, habit has generally been applied to recurrent forms of moral, economic, political, and religious conduct insofar as these occur more or less automatically, thus differing from reflective forms of human action that entail the deliberative selection of means and ends by normative standards. While the history of the concept of habit has been roughly coextensive with the entirety of Western intellectual history, four phases are distinguished. The first phase, running from antiquity to the early 1800s, was marked by the frequent discussion of the role and significance of habit by thinkers ranging from Aristotle to the philosophers of the Enlightenment. The second phase, extending from the mid-nineteenth to the early twentieth century, was characterized by two contending developments. One of these was the invocation of the concept of habit by a great many European and American social theorists, including Emile Durkheim and Max Weber, and the use of the concept, in tandem with models of reflective action, to analyze human conduct in the social world. The second development in this period was the effort on the part of natural scientists to restrict habit to more elementary human and subhuman behaviors. The third phase, beginning roughly in the late 1910s, saw the successful appropriation of habit, narrowly conceived, by behaviorist psychologists and, in a strong countermovement, the abandonment of the concept by a majority of European and American social thinkers, who for the next half century conceptualized all human conduct exclusively in reflective terms. The fourth phase, extending from the early 1980s to the present time, has witnessed steps by social theorists and empirical researchers to revive and elaborate the concept of habit and to examine the relationship between habitual and reflective forms of human action.

Found in ordinary languages the world over, 'habit' and various cognate expressions have functioned, for over two millennia, as concepts in diverse intellectual traditions in the social sciences, the humanities, and the natural sciences. As used in reference to various recurrent and relatively automatic forms of human conduct in the social world, "the discourse of habit is one of the great, albeit largely unacknowledged, cultural legacies of Western civilization" (Thomas, 1993: p. 8). Although the history of the discourse has been roughly coextensive with Western intellectual history itself, specific use of the concept, and explicit recognition of the aspects of human action to which it refers, have waxed and waned during different periods in the development of the social sciences.

The Concept of Habit

In the course of its lengthy history, habit has led multiple lives. Its origins lie in the unreflective, 'indiscriminate, quotidian use of habit' in various popular discourses, which are 'littered with offhand references' to habit (or to what is habitual, or done habitually) and which have historically furnished a vocabulary that has been imported into more rarified discussions of philosophical and scientific subjects. Students of biological life and the physical world have often used habit with reference to "non-human animals, the dynamics of populations, the growth pattern of plants, and the tendencies of systems." (For these quotations, see Sparrow and Hutchison, 2013: p. 3.) Applied to human conduct, 'habit' has generally designated a tendency or disposition for a person to act in ways that she or he has acted previously in similar contexts, insofar as that disposition is "activated automatically by the context cues that co-occurred" with the relevant action in the previous situations (quoting Neal et al., 2006: p. 198; see also Pollard, 2003: p. 411).

When these repeated actions are differentiated from one another in terms of their content, distinctions then arise between moral, cognitive, emotional, and motor habits. Of greater historical importance, however, has been another basis of differentiation. The actions whose repetition is designated as habit may range from simple and circumscribed to complex and generalized. Among the social thinkers who have used the concept, habit has most frequently been applied to recurrent patterns of action of moderate complexity and generality, i.e., to habits of economic, political, religious, and domestic conduct; habits of obedience to rules and to rulers; habits of sacrifice, disinterestedness, and restraint; etc. At various moments in the history of the concept, however, habit has taken on meanings both narrower and broader: sometimes, it has referred to simpler, or at least more elemental, behavioral regularities, such as habits of talking, walking, eating, dressing, routine problem-solving, etc.; at other times, it has been applied to the generalized and durable mode of action that a person may exhibit in one or more wider spheres of social life, such as work, politics, and interpersonal relations (or in all of these). When used in this more extended sense, the concept of habit has been largely synonymous with 'character' or 'habitus' – the latter is a term that traces back historically to the same linguistic roots as habit. The fact that habit has borne this entire range of connotations serves as a precaution against conflating particular notions of habit with habit as such. The assumption, prevalent in the middle decades of the twentieth century, that habit is a fixed, mechanical reaction to discrete stimuli and thus devoid of subjective meaning is, for example,

a view that has historically been associated mainly with habit in the sense of simple behavioral regularities, not with more complex habitual forms of action.

At no point has the vocabulary of habit been an autonomous discourse. To a significant degree, its usage has shifted over time because of the different ways in which habit has been combined with, or distinguished from, other concepts. At one important period in its history, habit functioned as the antithesis of instinct, such that all noninstinctual behavior was regarded as habitual. Prior to and subsequent to this period, however, habit was ordinarily set over against purposive, reflective types of action characterized by the deliberate selection of means and ends according to various cognitive and moral standards; in this case, habitual action served as the converse of those types of action foregrounded in reflective models of human conduct, such as those favored by many early- and mid-twentieth-century social scientists. At still other (albeit briefer) moments, however, habit has been taken not as the opposite of, but as the precondition for, reflexive action. The same flexibility of association has appeared with regard to moral conduct, which has sometimes been contrasted with habitual action, other times viewed as dependent upon it. Conceptual variability has been apparent as well at the collective level, where the common habits present throughout a social group have sometime been equated with 'custom,' whereas other usages define custom in terms of practices that result from adherence to established social prescriptions and are, therefore, distinguishable from actions that have become automatic owing to repetition or other habit-formation processes. (For a fuller treatment of the issues in this section, see Camic, 1986; Funke, 1958; Sparrow and Hutchison, 2013.)

Historical Development

Antiquity to the Early 1800s

The everyday discourse of habit was appropriated and rendered esoteric by Greek philosophers as they opened pathways for later social thinkers. In the *Nicomachean Ethics*, Aristotle laid it down that "none of the moral virtues arise in us by nature," that "we are adapted by nature to receive them and are made perfect by habit" (Book 2, Chapter 1) (Aristotle, 1973; for discussion, see Lockwood, 2013). The same conceptual vocabulary was incorporated into the philosophical and social teachings of Plato, Plotinus, Quintilian, Aquinas, William of Ockham, Luther, Montaigne, Pascal, Locke, and Wolff, among a great number of other philosophers, theologians, and men of letters; at the same time that generations of natural philosophers applied the concept in studies of physical and biological phenomena (Funke, 1958; Sparrow and Hutchison, 2013).

In the Age of the Enlightenment, as part and parcel of the emerging movement to create a 'science of man,' the concept of habit received renewed attention from a range of social thinkers who shared the belief that habit is a widespread and potent phenomenon in social life, even as they characterized this phenomenon differently. In France, Claude Adrien Helvetius (1715–71) celebrated habit as the wellspring of public and private morality and accepted it as a "principle by which [humans everywhere] are actuated" (Helvetius, [1758]1807: p. 57); in Scotland, Adam Ferguson (1723–1816) declared habit as the force "by which the good or bad actions of men remain with them and become part of their characters" (quoting Hill, 1996: p. 210); while from Prussia Immanuel Kant (1724–1804) held that "all acquired habits are objectionable" – that "virtue is moral strength in the pursuit of one's duty, which should never be a matter of habit" (Kant, [1798] 1978: pp. 32–34). David Hume, Thomas Reid, George Berkeley, Etienne Condillac, Jean-Jacques Rousseau, Johann Fichte, Friedrich Schelling, and G.W.F. Hegel were among the many thinkers who took part in this wide-ranging discussion (on the thinkers named here and others, see Camic, 1986; Funke, 1958; Sparrow and Hutchison, 2013).

An Age of Ferment

From the middle of the nineteenth century until the early decades of the twentieth century, the language of habit was an even more prominent intellectual presence. This was true in European as well as in American philosophical, natural scientific, and social scientific thought, sociological thought in particular.

In England, the concept of habit entered, with varying degrees of explicitness, into the work of a diverse range of thinkers that included Jeremy Bentham, James and John Stuart Mill, Herbert Spencer, Charles Darwin, Walter Bagehot, and Alfred Marshall; in France, into the writings of Jean-Baptiste Lamarck, August Comte, Alexis de Tocqueville, Frederic LePlay, and Henri Bergson; and in Germany, into the work of Friedrich Nietzsche, Ferdinand Tönnies, Georg Simmel, and Edmund Husserl, among many others. In the United States, the vocabulary of habit, which had long played significant roles in the teachings of popular social reformers, churchmen, and educators, was mobilized in new ways by the founders of philosophical pragmatism, C.S. Peirce, William James, John Dewey, and George Herbert Mead (see Shook and Margolis, 2009), by Darwinian natural scientists like Charles Whitman and Jacques Loeb, and by the first generation of professional, university-based social scientists. Among the latter were leading economists such as Francis Walker, Laurence Laughlin, and Thorstein Veblen, as well as all of the period's major sociologists, including Lester Ward, William Graham Sumner, Franklin Giddings, Albion Small, and W.I. Thomas.

In this respect, the doctrines of contemporary American sociologists accorded with those of the two towering European sociological thinkers of the same era, Emile Durkheim (1858–1917) and Max Weber (1864–1920). Durkheim's lifelong position, for example, was that "habits…are the real forces which govern us" (Durkheim, [1905–06]1956: p. 152). For him, as for the American pragmatists, human reflection is a process that generally "overloads or paralyzes action"; only "when habit is disrupted," and the individual or collective "being is … at a cross-roads situation [facing] a whole range of possible solutions," does reflection emerge in order to restore "equilibrium" and allow "habits of all kinds" to reassert themselves (Durkheim, [1913–14]1983: pp. 38, 79–80). Given this understanding, Durkheim constructed a program for the moral regeneration of modern society that relied heavily on the force of habit: on developing in children "the habit of self control and restraint" and "habits of group life"; on cultivating in occupational specialists "an absolute regularity in habits"

and "habits [of social interaction which], as they grow in strength, are transformed into rules of conduct"; and on instilling in society's leaders "a habitus of moral being" (Durkheim, 1902–03[1961]: pp. 149, 249, 1893[1984]: pp. 187, 302, 1904–05[1977]: p. 29).

Although engaged with very different intellectual questions, Max Weber voiced similar views. Concerned with the analysis of various forms of reflective action, Weber nevertheless insisted on the importance of habit, holding that "the further we go back in history, the more we find that conduct, and particularly social action, is determined in an ever more comprehensive sphere exclusively by the disposition toward the purely habitual"; and that "individuals are still markedly influenced" by this force "even today," when "the great bulk of all everyday action [continues to occur in the form of an] almost automatic reaction to habitual stimuli which guide behavior in a course which has been repeatedly followed" (Weber, [1922]1978: pp. 320, 337, 25 (modified translation)). Understood in this way, the concept of habit figured into Weber's treatment of economic, political, and religious traditionalism, into his writings on economic, political, legal, and communal action in the modern world, and even into his analysis of the process by which ascetic Protestantism promoted the rational spirit of modern capitalism. Regarding "the spirit of capitalism" as a "particular habitus," Weber credited the early Calvinists with creating, "out of their religiously conditioned family traditions and from the religiously influenced life-style of the environment, [a distinctive] 'habitus' among individuals which prepared them in specific ways to live up to the specific demands of early modern capitalism" (Weber, [1910]1968, [1910]1978: p. 1124).

As Weber, Durkheim, and their sociological contemporaries used the concept of habit to refer to forms of action of moderate as well as broader generality, however, natural scientists of the period increasingly associated habit with recurrent human and subhuman activities of much simpler and more mechanical kinds. This, for instance, was the practice of Jean-Baptiste Lamarck (1744–1829), and Charles Darwin (1809–82) following the example, regularly spoke of the flowering habits of plants, the feeding habits of insects, and the flying habits of pigeons (Darwin, [1859] 1964: pp. 11, 183; [1872]1975: pp. 29–31). This was also the practice of many European physiologists and psychologists as they turned attention to the study of the neural foundations of simple animal and human reflexes to external stimuli, invoking habit to describe neural pathways that were noninstinctual yet well established (see Fearing, 1930). This circumscribed usage gained wide currency among late-nineteenth and early-twentieth-century American psychologists, who shared with William James (1842–1910) the view that even "the most complex habits [are] nothing but concatenated discharges in the nerve-centres, due to the presence there of systems of reflex paths" (James, [1890]1950: p. 108). Taking up this same formulation and substituting it for various broader sociological usages, early twentieth-century American social scientists came to define the concept of habit in terms of "the physiology of the nervous system," a formulation that led them to argue that "education and social control are largely dependent upon our ability to establish habits" – habits thus conceptualized – "in ourselves and others" (quoting Park, [1915]1969; see also Camic, 1986).

The Demise of Habit

This important shift in usage was part of a broader social organizational change that occurred as the subject of habit became the object of ownership battles among university-based scholars situated in specialized – and competing – academic disciplines. Indeed, as members of different disciplines engaged in turf wars to differentiate their emerging academic fields from one another, habit assumed the role of a conceptual pawn, a role unknown to it in earlier pre-professional writings where proprietary rights to the concept were not yet in dispute.

The watershed in this development was the behaviorist movement, which engulfed American psychology in the early and middle decades of the twentieth century. Launched by John B. Watson (1878–1958) in an effort to invest the discipline of psychology with the prestige that then inhered in the application of concepts drawn from the natural sciences, behaviorism claimed the realm of habit as its core topic of investigation, asserting that *every* "mode of acting … not belonging to man's hereditary equipment must be looked upon as a habit" – habit understood in physiological terms as "muscular and glandular changes which follow upon a given stimulus." For Watson and his disciples, the corollary of this argument was that a mechanistic habit-psychology provided the way "to guide society…toward the control of group and individual behavior" (Watson, 1919: pp. 270, 14, 2–3) – from which corollary it followed that the academic discipline required for the genuine scientific study of the social world was "not [a social science like] sociology, but psychology," as it derives from "biology, chemistry, and the other natural sciences" (Allport, 1927: pp. 167–168).

Because these sweeping ownership claims directly challenged the bases of their own academic disciplines, social scientists (as well as humanists) from the period almost immediately recoiled from the language of habit, ceasing their use of a concept that had been central to their analysis of human conduct since antiquity. Eager to stop the behaviorist campaign to eliminate, as a valid object of scientific investigation, the reflective forms of action that had previously commanded recognition alongside habitual forms, sociologists of the era undertook an aggressive countercampaign to rescue purposive human conduct from assault. To accomplish this, they deliberately abandoned their prior use of the discourse of habit, thereby abruptly purging habitual phenomena from their conceptualization of human conduct in the social world. This purge was inaugurated by (a one-time proponent of the concept of habit) W.I. Thomas (1863–1947) and Florian Znaniecki (1882–1958), whose work attacked the "behavioristic school" for its "indistinct [application] of the term 'habit' to [all] uniformities of behavior" and insisted that 'habit' … be restricted to the biological field, [since] it involves no conscious, purposeful regulation of [conduct], but merely … is unreflective, [whereas] the uniformity [characteristic of social life] is not a uniformity of organic

habits but of consciously followed rules (Thomas and Znaniecki, [1918]1958: pp. 1849–1852).

Within a generation, this formulation became social scientific dogma, eliminating all sociological talk of habit and replacing it with the language of 'attitude,' which Thomas and Znaniecki had simultaneously ushered onto center stage and which subsequently furnished American social scientists with a new vocabulary for describing recurrent tendencies in human conduct but without sacrificing reflective action models as the behaviorists had done (Camic, 1986; Fleming, 1967). Analogous movements away from the concept of habit occurred in European social thought, as Durkheim and Weber themselves subtracted the concept from their work; and they occurred as well as in European and American humanistic literatures (Fisher, 1973; Thomas, 1993).

Following this conceptual sea-change, the discourse of habit lay dormant in the social sciences from the late 1910s to the early 1980s, a few isolated exceptions notwithstanding. Shortly after the start of the behaviorist revolution in psychology, John Dewey (1859–1952) insistently harked back to a broader conception of habit (1922), as Norbert Elias, Martin Heidegger, Jean Piaget, and Maurice Merleau-Ponty would subsequently attempt to do in Europe (Kestenbaum, 1977; Sparrow and Hutchison, 2013; and, for Elias, [1939]1994; see also Berger and Luckmann, 1966). But these philosophically oriented interventions failed to stem the behaviorist tide or the social-scientific rejection of the concept of habit that had emerged in reaction. Only among psychologists working in the behaviorist tradition, and among a few economists concerned with consumer behavior, did habitual phenomena remain the focus of empirical research during the long mid-decades of the twentieth century (Deaton and Muelbaur, 1980; Smith, 1986). Otherwise, social scientists simply dispensed with the concept, opting to conceive all human action as though it were a reflective process of selecting means to ends in accord with normative standards.

Recent Developments

The period from the 1980s to the 2010s has brought the onset of another reversal, however. Behind this recent development has been a change in the social-organizational conditions that led to the demise of social-scientific interest in habit during the previous historical era. By the closing years of the twentieth century, the intellectual turf warfare among disciplines that had marked the early to middle decades of that century was long ended, and its waning rendered increasingly anachronistic the behaviorists' proprietary claims on habit. The obsolescence of these claims, and of the counterclaims that they had called forth, freed up the concept of habit to reassume some of the broader connotations it once possessed and to reenter, with scarcely any resistance, the social-scientific analysis of human conduct.

To be sure, this revival of the language of habit has thus far been spotty and gradual, and it has left untouched many areas of the social sciences where the language might arguably be put to use. Even so, references to concept of habit and a renewed appreciation of the significance of the phenomenon have begun to reappear throughout the social sciences and the humanities, notably in the work of contemporary philosophers (Ostrow, 1990; Pollard, 2003; Shook and Margolis, 2009), social psychologists (Charng et al., 1988; Neal et al., 2006; Ouellette and Wood, 1998), and economists (Campbell and Cochrane, 1995; Carroll et al., 2000; Dynan, 2000; Fuhrer, 2000; Kahneman, 2003; Li, 2005; Shachar, 2003).

Moreover, just as they had previously spearheaded the assault on the discourse of habit, so sociologists have been particularly active in the current resurrection of the discourse. To varying degrees, this about-face has been evident in the writings of sociological theorists of several different persuasions, all of them of the view that habitual forms of action warrant inclusion along with reflective forms (Archer, 2012; Calhoun et al., 2012; Camic, 1986; Emirbayer and Mische, 1998; Giddens, 2009; Gronow, 2011; Joas, [1992] 1996; Schatzki et al., 2001; Martin, 2011; Sewell, 2005; Turner, 2010). Both explicitly and implicitly, this same view has come to inform research in the specialty areas of economic sociology (Biggart and Beamish, 2003; White, 2004), the sociology of organizations (Adler, 2010), the sociology of science (Collins, 2012), the sociology of morality (Hitlin and Vaisey, 2012), and the sociology of the body (Shilling, 2008). In a further development, sociologist Pierre Bourdieu (1930–2002) drawing on a previously neglected strand in the work of Weber and Durkheim, has resuscitated and elaborated the notion of habitus ([1980] 1990), setting it in place as one of the foundation stones of his oeuvre. Among scholars influenced by Bourdieu's writings, habitus has also crystallized as a major locus of theoretical inquiry and empirical investigation (Gorski, 2013; Hillier and Rooksby, 2005).

Although these numerous lines of recent work remain generally disconnected from one another after the first decade of the twenty-first century, their simultaneous emergence and likely future cross-pollination augur the return of the concept of habit to a position of centrality in social-scientific theory and research, and, accompanying this development, the transformation of exclusively reflective models of action into analytical approaches concerned with the complex and changing relationship between reflective and habitual forms of human conduct in the social world.

Abstract

Habituation is defined as a decrement in response as a result of repeated stimulation not due to peripheral processes like receptor adaptation or muscular fatigue. It is a process occurring within the nervous system (in animals with nervous systems). Habituation is definedin more detail by a number of parametric properties, involving such factors as stimulus frequency and intensity, pontaneous recovery of the habituated response, etc. Sensitization is defined as an increase in response as a result of (usually strong) stimulation.

Habituation primarily refers to stimulus-response systems that are 'hard-wired,' i.e., the stimulus elicits the response in the absence of any training, as in reflexes, fixed action patterns, arousal, etc. In neural systems where analysis has been possible, habituation is due to synaptic depression; a decrease in probability of transmitter release at appropriate synapses within the habituating circuit, and sensitization is an increase in the probability of transmitter release, due either to intrinsic or extrinsic processes. In vertebrates, at least, dishabituation, the disruption of habituation due to a strong extra stimulus, appears to be an independent superimposed process of sensitization. Habituation (and sensitization) appear to be ubiquitous in the animal kingdom and are extremely adaptive processes.

If a drop of water falls on the surface of the sea just over the flower-like disc of a sea anemone, the whole animal contracts vigorously. If, then, a second drop falls within a few minutes of the first, there is less contraction, and finally, on the third or fourth drop, the response disappears altogether. Here in this marine polyp with the primitive nerve net is clearly exhibited one of the most pervasive phenomena of the animal kingdom – decrement of response with repeated stimulation. Almost every species studied, from amoeba to man, exhibits some form of response decrement when the stimulus is frequently repeated or constantly applied. The ubiquity of the phenomenon plus its obvious survival value suggests that this kind of plasticity must be one of the most fundamental properties of animal behaviour. (Sharpless and Jasper, 1956, p. 655)

With these words, Sharpless and Jasper introduced their now classic study of habituation of the electroencephalogram (EEG) arousal response. Their study had a profound impact on behavioral neuroscience and served to kindle the interest of neural scientists in brain mechanisms of habituation. *Habituation* is a decrease in response to repeated stimulation, and *sensitization* is an increase in response as a result of stimulation. Virtually all behavioral responses, as well as autonomic and EEG responses and signs of arousal, habituate rapidly and to a profound degree. The processes responsible for habituation of behavioral responses probably occur largely after the primary sensory pathways of the brain and before the motor neurons that move muscles – somewhere between initial processing of sensory information and the execution of decisions to respond. Sensitization, the increase in response that often occurs when strong stimuli are given, may be similarly localized, although some evidence indicates that sensitization may occur in motor systems and motor neurons.

In early work on brain processes of habituation, it was thought that virtually all measures of neural activity might habituate, ranging from first-order sensory nuclei to the cerebral cortex. An early experiment to report evoked response habituation was that of Hernández-Peon et al. (1957); they recorded responses to click stimulation at several levels of the auditory system. Trains of clicks were delivered once every two seconds for long periods of time and evoked responses of the cochlear nucleus (the first relay of the auditory system) were reported to habituate.

Careful studies by Worden and associates (see Marsh et al., 1962) demonstrated that click-evoked responses at the cochlear nucleus do not show habituation. Instead, amplitudes of responses at this first relay nucleus in the auditory system are rigidly controlled by the physical properties of the sound stimulus. Because of acoustic factors, the intensity of a sound is often weaker at the floor of a test cage. If an animal gradually became bored and rested his head on the floor, the cochlear nucleus-evoked response to click would decrease because of reduced sound intensity.

In an extensive and careful study, Wickelgren (1968) found that habituation of evoked responses to auditory stimuli was not prominent below the level of the thalamus and cortex in the auditory system. This appears to be a general finding in all sensory systems – the lower ascending relay nuclei do not exhibit habituation. It would be most surprising if there were marked habituation in sensory systems. If our sensory systems habituated to sensory stimuli, we would rapidly cease to have sensation – a most unadaptive state of affairs. However, behavioral responses and phenomena that seem to be related to the probability of behavioral responding, such as EEG arousal and autonomic signs of orienting, show marked habituation. It is very adaptive to cease responding to arousing stimuli that have no particular significance.

Historically, such processes as habituation and sensitization were viewed simply as reflexes and not as phenomena of learning and memory. However, the broad definition of learning as a change in behavior as a result of experience certainly encompasses both phenomena. When this was recognized, analysis of neural mechanisms became 'legitimized' (Sharpless and Jasper, 1956; Thompson and Spencer,

1966). Habituation and sensitization are now seen as examples of nonassociative learning and memory. Greater progress has been made in analysis of the basic neuronal mechanisms underlying habituation than in more complex forms of behavioral plasticity such as classical and instrumental conditioning. Major reasons for this progress lie in the widespread occurrence of habituation, in its simplicity, and in the reliability with which the behavioral properties of habituation can be specified and determined. Habituation occurs both in spinal reflexes of the vertebrate (Sherrington, 1906) and for responses of simple animals, as well as in complex human behavior. Consequently, neural mechanisms of habituation can be studies in simplified systems.

As noted earlier, behavioral habituation is simply response decrement as a result of repeated stimulation. For example, if a moderate electric shock is delivered to the foot of a normal but restrained animal for the first time, the animal will show marked struggling and leg flexion movements. However, if the stimulus is repeated a few times, the responses decrease considerably and may even disappear. Habituation is commonly differentiated from response decrements due to trauma, growth, aging, etc. In the example above, if the shock to the foot is withheld for a period of time after habituation and then given again, the response will reappear with normal strength. This spontaneous recovery is a common control used to show that habituation is a *reversible* response decrement.

Response decrements due to altered sensitivity of receptors are often termed *receptor adaptation*, and response decrements due to decremental effects occurring at the neuromuscular junctions of muscles are often termed *muscular fatigue*. Neither of these processes is considered to be habituation; it is a central rather than a peripheral process. Almost all behavioral responses of the intact organism initially elicited by a given stimulus, ranging in complexity from leg flexion to exploratory and play behavior, show habituation with repeated stimulation.

Response sensitization may be defined simply as an increased response strength to a given stimulus as a result of some other, usually strong, stimulus. The galvanic skin reflex (GSR) is a good case in point. Suppose we were to measure the GSR activity of sweat glands in the palm of the hand in response to a sound of moderate intensity. The response would probably be of relatively low amplitude and somewhat irregular in occurrence. If a strong shock were delivered to the skin, the sound alone now would evoke a much larger GSR response; the response would have been sensitized. The response increase due to sensitization is distinguished from conditioning in that no pairing of shock and sound is necessary to produce the effect. Sensitization itself typically habituates; after a number of shock presentations the response to the sound decreases to the initial weak level. In fact, it seems to decay spontaneously following a sensitizing stimulus.

The study of habituation has a long history; some of its basic properties were described in classic works by Jennings (1906), Humphrey (1933), Prosser and Hunter (1936), and Harris (1943). Thompson and Spencer (1966) surveyed the by then very extensive behavioral literature on habituation and identified some nine basic parametric properties or characteristics exhibited by behavioral habituation.

Properties of Habituation

1. Given that a particular stimulus elicits a response, repeated applications of the stimulus result in decreased response (habituation). The decrease is usually a negative exponential function of the number of stimulus presentations.
2. If the stimulus is withheld, the response tends to recover over time (spontaneous recovery).
3. If repeated series of habituation training and spontaneous recovery are given, habituation becomes successively more rapid (this might be called potentiation of habituation).
4. Other things being equal, the more rapid the frequency of stimulation, the more rapid and/or more pronounced is habituation.
5. The weaker the stimulus, the more rapid and/or more pronounced is habituation. Strong stimuli may yield no significant habituation.
6. The effects of habituation training may proceed beyond zero or asymptotic response level.
7. Habituation of response to a given stimulus exhibits stimulus generalization to other stimuli.
8. Presentation of another (usually strong) sensitizing stimulus results in recovery of the habituated response (dishabituation or sensitization).
9. Upon repeated application of the sensitizing stimulus, the amount of dishabituation produced habituates (this might be called habituation of sensitization).

It is important to emphasize that these characteristics of habituation are simply the empirically observed properties in a wide variety of behavioral studies on many species and as such do not imply particular theories or inferences. These properties have come to serve as the detailed definition of habituation. Thus, any particular stimulus-response system is said to exhibit habituation if the response decrement to repeated stimulation exhibits these properties.

The most potent variables determining the course of habituation are stimulus frequency and intensity. The frequency range must be behaviorally relevant. Very high frequencies can yield fatigue, potentiation, and other processes. The range of stimulus frequencies over which habituation occurs, i.e., behavioral response decrements exhibiting the properties noted above, is an empirical question dependent upon the organism, the stimulus, and the response system engaged. For the orienting or arousal response, the effective range may be from minutes to hours to days; for the spinal flexion reflex, the range is over seconds.

The fact that rate and degree of habituation are inversely related to stimulus intensity (property (5)) is true if the same intensity is used for test and habituating stimuli (the test stimulus is given sufficiently infrequently that it does not by itself cause habituation). However, if the test and habituating stimuli differ in intensity, more complex effects can occur (Davis and Wagner, 1968).

Dishabituation vs. Sensitization

Thompson and Spencer (1966) employed habituation of the spinal flexion reflex, first used as a model system to study habituation by Prosser and Hunter (1936), to characterize

the detailed properties of habituation and analyze possible neuronal mechanisms. They discovered that the process of 'dishabituation' caused by presentation of a strong extra stimuli was not in fact dishabituation. That is, it did not disrupt the process of habituation at all. Instead, it added a superimposed, independent process of increased excitability, namely sensitization. The fact that dishabituation, per se, does not appear to exist as such, but rather reflects a separate process of sensitization, appears to hold for all vertebrate preparations studied, ranging from reflexes to the startle response to EEG arousal and the orienting response. One exception to this rule has been reported for a monosynaptic system in the invertebrate *Aplysia* (Marcus et al., 1988). However, the neuronal mechanisms underlying the processes of sensitization/dishabituation appear to differ in vertebrates vs. the *Aplysia* circuit. In the latter, 'dishabituation' appears to be a presynaptic process, occurring at the sensory neuron terminals on the motor neurons (see Sect. 3 and Kandel, 1976); whereas, at least in spinal reflexes, sensitization can involve increased excitability in motor neurons (Thompson and Spencer, 1966). Actually, recent evidence suggests that changes may occur in motor neurons in the *Aplysia* circuit as well (Murphy and Glanzman, 1997).

The fact that dishabituation does not exist as such, but rather reflects a separate independent process of sensitization in vertebrate preparations led Groves and Thompson (1970) to develop the dual-process theory of habituation: the outcome of repeated stimulus presentations is due to the net interaction of the inferred processes of habituation and sensitization. This theory is able to account for an astonishingly wide range of behavioral phenomena (see, e.g., Peeke and Herz, 1973).

A somewhat differently construed and widely influential theory of habituation is the stimulus-model comparator theory developed in Russia by Evgeny Sokolov (1963), based largely on data from the human orienting response. In this view, repetition of a given stimulus results in the development of a neuronal 'model' of the stimulus in forebrain structures. If a repetitive stimulus matches the model, then there is little output, only the habituated response, which could be no response, i.e., no EEG arousal. However, if there is a mismatch, then the difference is amplified via the reticular formation and a larger response results.

The dual-process theory is more successful in accounting for basic phenomena of habituation and sensitization in a wide range of species; the modelcomparator theory can more easily account for more complex phenomena like the 'missing stimulus' effect (increased response to the absence of one presentation of the habituating stimulus, a phenomenon sometimes seen in EEG arousal but not in reflex systems). But note that a process of synaptic depression could underlie the formation of the neuronal model of the stimulus in the model-comparator theory; the theories are at different levels and not incompatible. A view somewhat similar to that of Sokolov was developed by Wagner (1979) to account for long-term habituation. Thus, the central model of the habituating stimulus is considered as a relatively long-term memory trace, yielding the basic properties of a learned response. In their classic study of human EEG arousal habituation, Sharpless and Jasper (1956) stressed the distinction between short-term and long-term habituation.

As noted earlier, primary sensory afferent system neurons do not exhibit habituation. This makes perfect sense; in order to 'decide' how much to respond to a stimulus it is necessary to know what the stimulus is. Virtually all behavioral responses elicited by stimuli show habituation to repeated stimulation under at least some conditions. Central brain processes that are behavior-related like cortical EEG arousal show clear habituation, as do brain motor systems. Davis and associates completed a comprehensive analysis of the startle circuit and startle habituation in the rat (Davis, 1984). The circuit includes auditory relay nuclei: the cochlear nuclei and the nuclei of the lateral lemiscus; a nucleus in the brainstem reticular system (nucleus reticularis pontis caudalis) and its projections to brainstem and spinal cord premotor and motor nuclei. Evidence suggests that habituation to the acoustic startle stimulus occurred before the motor systems, i.e., at the nucleus reticularis pontis caudalis (Davis et al., 1982). The reticular nucleus is a 'bridge' nucleus between sensory and motor systems.

Neural Mechanisms

Unlike associative learning, in habituation the stimulus-response neuronal circuit is hardwired. In systems where some degree of analysis of neuronal mechanisms is possible, the neural substrate of habituation occurs within the stimulus-response circuit itself and is not due to any extrinsic circuit action like external inhibition acting on the habituating circuit.

Greatest progress in analyzing neural mechanisms of habituation and sensitization has come from simplified neuronal systems. Two of these are the gill withdrawal reflex of the mollusk *Aplysia* and vertebrate spinal reflexes. Kandel (1976) and his many associates completed a detailed analysis of the processes of habituation and sensitization in the *Aplysia* monosynaptic circuit. They were able to show that habituation was a presynaptic process involving a decrease in the probability of neurotransmitter release as a result of repeated activation. Similarly, a process of synaptic depression is responsible for habituation of the tail-flip escape response in the crayfish, another very productive invertebrate model system (Krasne, 1969). In the *Aplysia* model, synaptic decrement is due to a persisting decrease in calcium ion influx into the terminals. Sensitization, elicited for example by strong shock to the tail of the animal, was due to activation of a polysynaptic circuit that acted presynpatically on the sensory neuron terminals, the same terminals that habituated. The effects on calcium channels are due in turn to complex and not fully understood biochemical cascades within the neurons. Kandel and associates have also described a long-term sensitization effect involving structural changes in the synapses that they have used as a model for long-term memory storage (Hawkins and Kandel, 1984).

In the vertebrate spinal cord, the flexion reflex is polysynaptic. Thompson and Spencer (1966) were able to rule out any changes in excitability in the sensory neuron terminals and in the motor neurons themselves during habituation. However, sensitization did involve increases in motor neuron excitability, as noted above. They suggested, but could not prove, that a process of low-frequency depression in the interneurons was responsible

for habituation, a process analogous to the presynaptic depression process demonstrated by Kandel and associates in *Aplysia*. Using a monosynaptic pathway in the isolated frog spinal cord, Farel and Thompson (1976) demonstrated a presynaptic process for habituation. The story concerning neuronal mechanisms of habituation is particularly satisfying because the same process of synaptic depression appears to underlie habituation in both invertebrate and vertebrate systems. This simple process of synaptic decrement can account for a wide range of behavioral phenomena of habituation.

The study of habituation continues to be a most active field of research, ranging from responses of nematode C. *elegans* (Wicks and Rankin, 1996) to the startle response in mammals (Pilz and Schnitzler, 1996) to behaviors in the human fetus and infant (Leader, 1995, Kaplan et al., 1990).

Habitus: History of a Concept

Abstract

Borrowed from the Aristotelian–Thomist tradition, the concept of habitus was occasionally used in sociology and philosophy to designate an acquired and stable disposition. While phenomenologists (Husserl namely) were interested in its role in the construction of the self (ego) through past experience, it served sociologists such as Weber and Elias in their reflection on the collective dimension of attitudes and behaviors shared by a social group, be it religious (Weber) or national (Elias). Drawing from these two traditions of thought (phenomenology and sociology), Bourdieu theorized this concept, relating it to his theory of practice, which emphasizes the process by which individuals interiorize habits in their body through education. Bourdieu applies the concept of habitus to social classes and their differing lifestyles.

Designating an acquired disposition characterized by its stability, the concept of 'habitus' originally derives from the Aristotelian–Thomist tradition. Whereas medicine appropriated it to signify ways of being, and sickly states in particular, by their external manifestations (general physical and facial demeanors), the emerging field of sociology (notably Weber, Mauss, and Elias) designed it into a tool to conceptualize the incorporated form of collective habits, which vary from one society to another. Phenomenology, and Husserl in particular, employed it to think about the characteristics of the self constituted by past perceptions and decisions, which have settled into a prereflexive state of consciousness. These two traditions were synthesized by Pierre Bourdieu, who developed the 'habitus' into a chief notion of his sociological theory, linking it with his theory of practice.

From Scholastic Philosophy to Phenomenology and Sociology

The concept of habitus, derived from the Latin verb, *habere*, first appeared in scholastic philosophy in the sixth century in the work of Boèce, as a translation of Aristotle's 'hexis,' which signifies the positive dimension of 'the habit,' which is guided by reason and constitutes a virtue, unlike the ethos, which refers to the passive repetition of acts. It is reappropriated in the thirteenth century by Thomas Aquinas, particularly as he examines the ways of acquiring faith in the *Summa Theologiae*.

Max Weber employs this concept in the context of his sociology of religions to designate the psychological state that the good of salvation bestows upon the religious person, and which, notwithstanding the projection in the afterlife that it implicates, is a "habitus of the present" (Weber, 1996, p. 346). In his introduction to *The Ethical Economy of World Religions* (1915–20), Weber describes the "affective habitus" of the ascetic engendered through the specifically religious (or magical) act, through asceticism or contemplation (Weber, 1996, p. 347). He sets the active religious habitus that characterizes the West against Eastern traditions, which he describes as more contemplative. As he explains in the chapter of *Economy and Society* dedicated to religion, the rationalization of the appropriation of the goods of salvation consisted in eliminating the contradiction between the daily religious habitus and the extraordinary religious habitus, and in thereby assuring the continuity of the religious habitus (Weber, 1996, p. 189). The continuous and conscious religious habitus has become, in the religions of Salvation and Deliverance, a method of religious salvation that seeks to mitigate the inebriety attained through orgy (Weber, 1996, pp. 183–189). Thus, as the sorcerer requires rapture and a habitus defined by permanent charisma, for the prophet, orgiastic inebriety runs contrary to an ethical way of life. Instead of a sacred state reached through inebriety, asceticism, or contemplation, it is precisely the 'sacred habitus' that will ensure the salvation of individuals. If, in *The Protestant Ethic and the Spirit of Capitalism* (begun in 1904 and completed in 1920), the term does not appear more than twice, and always with respect to the religious habitus (Weber, 2008), Weber uses it in his response to criticisms of the work in order to name that which drove protestants to adopt behaviors in accordance with primitive capitalism, and which found its origins in their religious life, family tradition, or lifestyle imbued with religiosity (Weber, 1996, p. 155). He also wields this concept on several occasions in *Hinduism and Buddhism* (1915–20) to designate certain states leading to salvation, and particularly that of nirvana, the habitus attained once one's ties to the world are severed.

The Weberian definition is imbued with the concept's original Thomist meaning, in so far as it refers to a virtuous way of life based on deliberately adopted habits.

During the interwar period, the concept acquired a more encompassing meaning, which was no longer restrained to its religious dimension, and which came to also include habits. While phenomenology emphasized individual consciousness in its relationship to the surrounding world, sociology invested its interest in collective consciousness and transmission.

Preferring the concept of habitus to that of habits as a heuristic tool wielded to reflect upon the properties of the 'ego' ('Ich'), Husserl uses it in *Erfahrung und Urteil* (1939), translated in English as *Experience and Judgment* (1973), to refer to the way in which perception remains intentionally attached to an object beyond the first experience that it has of that object, transforming itself into latent knowledge capable of

 http://dx.doi.org/10.1016/B978-0-08-097086-8.03085-3

reactivating itself each time it encounters the said object. This concept thus simultaneously disagrees with empiricism and inneism, for it supposes that perception is structured by an acquired knowledge about objects situated "*on its horizon* of typical familiarity and precognizance" (Husserl, 1939/1973, p. 122). This is why Schütz translated the term habitus as employed in Husserl's work with that of 'habitual knowledge.' The ego is a 'substrate of habitualities,' explains Husserl in *Cartesian Meditations* (Méditations cartésiennes, originally published in French in 1931): the term habitus, which appears twice in the work (in sections 27 and 32), extends its scope to include decisions taken in the past and transformed into beliefs, convictions, which inform me, constitute myself as a stable and abiding ego, forming one's "personal character," according to Husserl's expression, or one's individual "style," to cite a term he also uses (Moran, 2011, p. 61). In this last work, as in *Ideen II* (1952), Husserl insists on the double dimension, passive and active, of the habitus: On the one hand, there is prereflexive daily action, and on the other hand, there is critical reflexive activity, which has a grip on the former, for instance the decision one may take to retain a belief (the second sort of habitus underpins the 'theoretical habitus,' which Husserl attributes to the scholar and the philosopher).

This double dimension is also central in the (nonsystematic) usage that Merleau-Ponty (1945/1976) makes of this concept. It was above all against behaviorism, which reduces action to simple reactions to stimuli (reflexes), that the French phenomenologist, nourished by his readings of Husserl, developed his reflection on the habitus as a disposition, comparable to a productive synthesis rather than the simple residue of past experiences. However, by contrast to Husserl, the author of *The Structure of Behavior* (*La Structure du comportement*, originally published in 1942) situates this knowledge in the body and no longer in consciousness. Neither automatism nor interiorized knowledge, the habit is "in the hands" (Merleau-Ponty, 1945/1976, p. 168). It is, as in a dance, through the kinesthetic grip that learning is accomplished, it is the body that 'understands.'

Foregoing a systematic usage of the concept, Durkheim and Mauss integrate it into their reflection on the process of 'socialization,' or, in other words, the inculcation on young generations through their education of 'systems of ideas, sentiments, and practices' specific to the groups to which they belong, such as "religious beliefs, moral practices and beliefs, national or professional traditions, and collective opinions of every kind," as Durkheim writes in 1911 in an article on "education, its nature, and its role" (Durkheim, 1922, p. 51; English trans. 1956, p. 72). Explaining the idea of conversion as invented by Christianity in *The Evolution of Pedagogy in France* (*L'Évolution pédagogique en France*, 1904–05), Durkheim uses the concept of habitus to qualify a "general disposition of the mind and will": a "habitus of moral being" (1938, p. 37; English trans. 1977, pp. 28–29). In his 1937 article on the "techniques of the body," Marcel Mauss also introduces the bodily dimension of the concept. According to Mauss, the term 'habitus' translates better than 'habit,' Aristotle's notions of the 'existing,' the 'acquired,' and the 'faculty.' Contrary to the theory of Gabriel Tarde, for whom the shared practices result from imitation, it is, according to Mauss, through education, and particularly through the training, the molding of the body, that are internalized and incorporated, not only social representations, but also rules of conduct and practices.

The term 'habitus' appears occasionally under the pen of Max Scheler, who, in *Formalism in Ethics* (1911), describes the 'habitus' of the chauvinist as being identical in every country, manifesting the same discourses and the same attitudes, and thus debunking the idea that the individuation of nations implies a different sort of nationalism. It is not certain whether this usage, which is closer to the common understanding of the term in German (manner, attitude) than it is to scholarly usages of the concept as developed in the work of Weber or in the Aristotelian–Thomist tradition, was a source for Norbert Elias' reflection on the national habitus. In his work, *Uber den Prozess der Zivilisation* (1937), translated into English as *The Civilizing Process*, Elias evokes the 'psychological habitus of civilized peoples,' with respect to the discussion of notions of culture and civilization, through which French and German customs and traditions came to distinguish themselves from one another. In *The Society of Individuals* (1939), Elias employs the term "habitus" to designate the way in which a particular form of "behavior-control" crystallized into a "character" or a "psychological individual habitus" (Elias, 2010, p. 41). Elias went on to systematize his usage of the concepts of 'social habitus' and 'national habitus' in the 1980s, after the notion was developed and popularized in the works of Bourdieu. The social habitus shared by the individuals of a same group is the expression of the particular forms of civilization characteristic of that group, as Elias expresses in an essay on the notion of civilization, written in 1986 (Elias, 2010, p. 5). In a text entitled, "Changes in the We–I balance" (1987), in which he describes how he relies on the concept of "social habitus" – that he sometimes likens to Kardiner and Linton's concept of the 'personality structure' – in order to overcome the opposition between individual and society, he explains how in differentiated societies, this social habitus is composed of several strata. In constituted nation-states, the national habitus takes precedent over regional belongings, while in modern states still in the process of construction, the contrary occurs. That national habitus hampers European unification (Elias, 2010, pp. 164, 188, 197). In *Studien über die Deutschen* (1989), he seeks to comprehend German nationalism in order to understand the rise of Nazism and what he calls the process of 'decivilization,' all while taking into account differences between classes and social groups. Far from being fixed, this national habitus, which Elias distinguishes from the essentialist notion of 'national character,' transforms itself through the process of intergenerational transmission. According to him, the advent of Nazism can be explained by a long experience of submission to autocratic regimes, closely associated with a code of obedience within a hierarchical structure: "The anchoring of an autocratic form of rule in the habitus of individual people kept on creating a strong desire for a social structure corresponding to this personality structure" (Elias, 1989/1996, p. 69).

Religious habitus, group habitus, national habitus, all of these sociological usages have in common the idea that certain durable dispositions fundamentally characterize groups of individuals within which it is transmitted, and which vary across space and/or time. Bourdieu would go on to apply this concept to class differences.

Pierre Bourdieu's Theory of Practice

The concept of habitus constitutes a key element in the sociological theory of Pierre Bourdieu, in that it founds his conception of action as much as his notion of the perception of the world. It is also at the heart of his analysis of social relations and lifestyles that structure the social space. This concept and the theory of practice that he associates with it were elaborated during a conjuncture in the social sciences defined by a critical paradigm shift. Although a bit younger, Pierre Bourdieu indeed belongs, alongside Louis Althusser and Michel Foucault, to the generation that constituted and affirmed itself against the branch of existentialism that then predominated in the intellectual field, pitting against a 'philosophy of the subject,' a 'philosophy without subject,' challenging the reigning subjectivism with the objectivism of the structures, setting against existentialist or 'personalist' humanism, what was then referred to as an 'antihumanism.' Against the rationalist tradition that, from Descartes to Sartre, posits consciousness' transparency to itself, the emerging social sciences, in the wake of psychoanalysis and Durkheimian sociology, honed in upon the gaps between actions agents undertake and the consciousness they have of them, which supposes an unconscious whereby the individual is acted upon more than he or she is acting, without necessarily reducing human behavior to a series of reactions to stimuli, as does behaviorism.

Nourished by the studies he undertook in Algeria and in Béarn between 1958 and 1960, then in France in the 1960s, as well as by his readings of Sartre, Merleau-Ponty, Husserl, Heidegger, Durkheim, Mauss, Saussure, Lévi-Strauss, Marx, Weber, Panofsky, Chomsky, Wittgenstein, and so on, the theory of 'habitus' progressively elaborated by Pierre Bourdieu during that period, participates in these questionings, to which it offers an original response: Seeking to overcome the contradictions between objectivism and subjectivism, mechanism and finalism, structures and individuals, etc., it reintegrates the experience of agents as partaking in social reality without searching therein the full explanation of their actions, the entire meaning of which is bound up in the system of hierarchical and structured relations within which they take place. Above all, Bourdieu's 'habitus,' following in the tradition of Mauss and Merleau-Ponty, places the body at the core of the individuals' capacity to produce a series of responses more or less adjusted to various situations.

The notion of 'habitus' appeared for the first time under Bourdieu's pen in a 1962 article on celibacy in Béarn, in which he referred to Mauss' article on the 'techniques of the body': describing a ball where peasants stand on the sidelines while the girls dance with the boys from the city, he explains that their habitus, that is to say, their physical properties – physical force, solidity, attachment to the earth – which served to their advantage in the precapitalistic era, came to constitute a handicap for the process of reproduction, as demonstrated in their inability to dance. The concept reappeared in 1967 in his postface to the French translation of Erwin Panofsky's *Gothic Architecture and Scholasticism*, which Bourdieu published in the series *le sens commun* of which he was the editor at Les Éditions de Minuit. According to him, Panofsky's approach, which illuminates the shared structural foundations of gothic architecture and scholastic thinking, allows the reader to grasp "the collectivity at the very heart of individuality, in the form of culture," that is to say, "the habitus by which the creator participates in and of his collectivity and his epoch, and which orients and directs, in spite of him, his acts of creation that appear to be the most unique" (Bourdieu, 1967, p. 142; free translation). Bourdieu directly draws upon Panofsky's concept, which its author himself derived from Thomas Aquinas, *The Sum* serving as his model of scholasticism. Bourdieu defines the habitus as a grammar generative of the thinking, perceptions, and behaviors that characterize a culture, by analogy with Noam Chomsky's notion of generative grammar in linguistics. However, for Bourdieu's habitus, this generative capacity is not innate, as it is for Chomsky's grammar, but, rather, is socially acquired through education. In this regard, Bourdieu refers to Durkheim and Mauss' classic article on "*The Primitive Forms of Classification*" (1903/2009). The site of this habitus' transmission and inculcation, which helps to explain the structural homologies between activities as different as the construction of cathedrals and scholastic philosophy, is school. Panofsky's approach invites us to seek for the 'modus operandi' (method of operation) of practices, how they produce the work, rather than the mere decoding of the 'opus operatum' (the work wrought).

It is in *Outline of a Theory of Practice* (*Esquisse d'une théorie de la pratique*, 1972) that Bourdieu first delivered a complete elaboration of his theory of practice, which he went on to reformulate in more systematic terms in *The Practical Sense* (1980a). His reflection on practice is anchored in a double criticism of objectivism and subjectivism. Against the mechanistic visions of structuralism and Marxism, which posit agents as mere conveyors of structures or executors of rules or roles, Pierre Bourdieu reintroduces the finalistic conception dear to phenomenology, which describes behaviors and modes of conduct as oriented with respect to objectives and underlines their meaning, just as he reintroduces the subjective point of view of agents, which, if it does not fully account for their conduct, definitely guides and inflects it. From this line of approach emerged the notion of strategy, another key concept of Bourdieu's theory, which helps to reinvest agents with a certain amount of inventiveness and improvisation, and to explain their attitudes in relation to their perception of the possibilities offered to them and, in particular, to the extent to which they perceive such possibilities as probable, as well as to their subjective hopes, more or less adjusted to their objective opportunities (Bourdieu, 1987, p. 75sq). Bourdieu reproaches structuralism for its 'juridicism,' which, according to him, constitutes an intellectual bias: The researcher tends to project the model he himself has constructed into the minds of agents without problematizing the distance that exists inherently between theoretical reconstruction and practice. This confusion can also be observed in the polysemous use that structural anthropology makes of the notion of 'rule,' between a norm that agents would consciously follow, a principle that would unconsciously guide them, and a model constructed by the researcher to explain the regularity of practices. Similarly, the structuralist theory appears insufficient to Bourdieu as a means of explaining the gift and countergift exchange, most notably because of the temporal gap that ensures that the giver can never fully know what the countergift will be. This temporal gap, which also occurs in the challenge and to

the riposte, opens a space for agents to develop strategies more or less adjusted to situations, following the rules of honor.

However, although trained in phenomenology, Bourdieu never intended upon returning to the ultrasubjectivist finalism of Sartrian philosophy, or to an intersubjectivity that ignores the objective conditions of existence and the weight of the structures within which agents are taken. He rejects subjectivist approaches, which, from Sartrian existentialism to the theory of the rational actor, suppose that action is the product of the will of a conscious subject capable of projecting himself/herself into the future as he/she anticipates the consequences of his/her actions. He simultaneously contests the idea of total freedom of choice and that of unbridled projection into the future. Drawing on Husserl's notion of 'protention,' he distinguishes between long-term rational planning constructed around a future project (the education of children, for example), which characterizes capitalistic societies, from "practical aiming at a yet-to-come inscribed in the present, thus apprehended as already there and endowed with doxic modality of the present," which prevails in traditional societies, organized around a cyclical calendar (Bourdieu, 1987/1990, p. 12).

The concept of habitus, conceived of as the generative principle of individual practices, designates the capacity of agents to orient themselves in the social world and to adopt modes of conduct adapted to their objective conditions of existence without explicitly adhering to a rule, to improvise attitudes adjusted to the situation at hand, just as a speaker is capable of producing an infinite number of sentences, with only a few rules as his/her guiding framework, and without speech being reducible to language. This concept is also what permits us to overcome the alternative between mechanistic approaches and finalism by lending an inventive dimension to structures that have been incorporated in the form of dispositions. In large part determined by past experiences, the habitus implies a degree of incertitude, of openness, and a capacity for adapting to change. It is also linked to the logic of practice, and thus to a certain vagueness and fluidity.

In Chapter 3 of *The Practical Sense* (*Le Sens pratique*, 1980a), entitled "*Structure, Habitus, Practice*," Pierre Bourdieu proposes that the reader thinks about practices and representations as constituting the product of a process undergone by individuals whereby they interiorize the social structures in the form of dispositions. These systems of dispositions, which compose the habitus, are 'structured structures' therewith rendered structuring structures. These structuring structures are schemes of perception, action, and evaluation that orient the agent's vision of the world and individual modes of conduct in conformity with the groups to which they belong (Bourdieu, 1980a, pp. 88–89). Thus, the modes of conduct of individuals belonging to a particular group are regulated, orchestrated, without necessarily following a particular rule, or being explicitly concerted.

The conditions whereby such dispositions are acquired through education explain the adjustment that occurs between incorporated structures (dispositions, habitus) and objective structures (things, institutions). Following in the line of Durkheim, Bourdieu conceives of social facts as ways of being, thinking, and acting that are more or less instituted, like in the law, and more or less solidified in things. There is thus not a difference of essence between incorporated structures and objective structures, two forms through which social life manifests itsef (Bourdieu, 1980b, p. 7). Furthermore, the most ritualized or objective forms of social life are nothing else than codified practices that have been institutionalized.

The illusion of immediate comprehension as evident, which characterizes the practical experience of the world, its being taken for granted, is the fruit of that adjustment between objective structures and incorporated structures. It also founds the practical sense, that is, the capacity to adopt conducts that are objectively adapted to situations without mechanically obeying any specific rule. This theory allows one to thereby explain the correlation that tends to be observed between objective probabilities and subjective hopes, but also the disparities that can occur between these in cases of dissonance between dispositions and structures, in periods of crisis, social change, or confrontation with another culture: Bourdieu evokes in this regard the inertia effect – or hysteresis – of the habitus, which resists change, and which often brings about sanctions as illustrated in the emblematic figure of Don Quichotte. The capacity to adjust to new structures differs according to social groups and the dispositions of individuals: Bourdieu (1977) compares, for instance, the attitudes of Algerian subproletariat workers who, unlike workers benefiting from the stability of an employment and thus more apt to adapt themselves to a capitalist temporality, are incapable of projecting themselves into a rational future and tend, as a result, to have recourse to a magical interpretation of the world. The illusion of an immediate comprehension of the world is also at the origin of the blindness that tends to prevail with respect to the principle that founds this very illusion and of a certain resistance to history, that is to say, to the study of its sociogenesis, which is nevertheless the only approach that can denaturalize it.

The inertia of the past makes itself felt through habits embedded in the body. The socialized body thinks, it is a 'habituated' body, as Bourdieu explains in *Outline of a Theory of Practice* (Bourdieu, 2002, p. 297). The body is temporally structured by the work of pedagogy, which consists in teaching it to defer pleasures, to domesticate its impulses (to transform hunger into appetite, etc.). However, the body is also the site of practice, invention, and improvisation. This faculty for improvisation remains nonetheless limited by the agents' conditions of socialization, the habits they have incorporated that often pose resistance – a manifestation of their inertia – to the most conscious efforts they make to acquire mastery over their bodies. All while taking into account this faculty for improvisation, which need not be grasped by reflexive consciousness to operate in an efficacious manner, the concept of habitus thus traces the limits of the freedom of action and of the symbolic mastering of practice.

The concept of habitus allows us to move on from 'practice' as a concept to practices and to their principles of differentiation. In class-based societies, groups of individuals are differentiated by their practices – alimentary habits, practices of consumption, ways of dressing, cultural practices, voting, etc. These practices are strongly linked among themselves and form lifestyles, manifestations of class-based habitus, but they are also differentiated according to the predominance of economic or cultural capital, as Bourdieu demonstrated in *Distinction* (1979). These differences assume their full meaning in a system of cultural oppositions that found principles

of classification that agents enact in their daily judgments of others' behaviors (for example, distinguished/vulgar, elegant/rude, etc.). Far from being invariable, the practices that characterize groups can evolve and even acquire 'nobility' when they are adopted by the dominant classes (like the punk style that has been introduced into high fashion) or become banal when they are vastly diffused (such as the practice of tennis).

Bourdieu distinguishes between the primary habitus, acquired by the child in the household, and the secondary habitus, acquired at school. The schemes of perception, action, and evaluation transmitted by the educational institution are closer to the culture of the dominant classes than to the culture of the dominated classes. The contradictory dispositions that form the primary and the secondary habitus of individuals belonging to the dominated class may produce what he calls a 'cleft habitus.' Such a cleavage within the individual habitus can also result from migration (cleavage between national habitus in Elias' terms) or from contradictory habitus within the family, for instance, between the values of the dominant fractions of the dominant class and those of its dominated fractions, as in the case of the French painter Edouard Manet to which Bourdieu devoted a study (Bourdieu, 2013).

As a 'sense of the game,' the 'practical sense' is also what is at work in the encounter between a habitus and a field (Bourdieu, 1980a). Indeed, far from concerning only ritualized practices, the logic of practice also prevails in intellectual and creative activities. Practical learning plays a major role in the preparation undertaken for artistic professions (art, music, dance), alongside a theoretical training that, indeed, does not always provide the tools for symbolically mastering practice. This is why the 'creative project,' an extreme expression of intentionalist theories, does not suffice in attempting to account for an artist's work, as Sartre would have it. The encounter between the habitus of a cultural producer and the space of possibilities that his or her field offers him or her is a much more powerful explicative principle, which allows one to make the connection between internal and external analyses of works, on the basis of a theory of practice that emphasizes the modus operandi rather than the opus operatum, even for an art as little taught as literature (Bourdieu, 1994, pp. 59–99). This theory of practice thus provides the basis for a general theory of action that extends from the most ritualized to the most inventive forms of action without a break in continuity.

The concept of habitus, which was largely discussed and appropriated by a number of researchers of different disciplines, earned Bourdieu the accusation of determinism, pronounced by certain critics who opposed him with the idea of 'agency,' without so much as noting that this capacity to act was in fact at the very core of the concept of habitus and manifested itself precisely in the form of strategies. The notion of habitus is more sociologically precise than that of agency because it allows for the definition of types (more or less conscious) of agency, its variation according to groups and individuals, according to their dispositions and to their trajectories, as well as the limitations that this capacity comes up against (interior, as well as exterior). At odds with rational choice theory, the concept of habitus enables us to understand how individuals are able to conduct their lives without always being reflexive, how they remain to a certain extent caught in their past experiences, and how they are – more or less – able to adapt to change.

Abstract

Halévy was a French scholar whose original background in philosophy yielded a mode of analysis based on the Platonic dialectic which, together with his intense liberal perspective, provided a consistent core to his entire work. He examined the English Utilitarians, counterposing the laissez faire fundamentals of their economic theory with their panoptic emphasis in the judicial sphere. His subsequent study of Methodism's political moderation identified an underlying contradiction between Wesley's doctrine of egalitarian salvation and Methodism's hierarchical and disciplined structure. Finally, his study of European socialism identified the antinomy between the goal of liberty and the imperative of a compulsory organization of society. As he contemplated the onset of an 'era of tyrannies' in Europe, his liberalism was increasingly tinged with pessimism.

Élie Halévy was a French historian and philosopher who made three principal contributions to the social sciences: a study of the English Utilitarians; a historical account of English society in the eighteenth and nineteenth centuries, which is noteworthy for the role it attributes to Methodism and Evangelicalism in maintaining political stability; and an analysis of the development of European socialism culminating in what he designated an 'era of tyrannies.'

Biography

Élie Halévy was born at Étretat in Northwestern France to wealthy, artistic parents on 6 September 1870, a time which marked a turbulent period in French history, with the origins of the Third Republic, France's defeat by Prussia, and the collapse of the Paris Commune. Halévy's grandfather Léon Halévy, who was of Jewish descent, had been a disciple of Saint-Simon and succeeded Auguste Comte as his secretary for a time and he collaborated with Saint-Simon on his final works before Saint-Simon's death in 1825. Halévy's father was a successful librettist for such composers as Bizet and Offenbach, and his mother was of Swiss Calvinist origins. Both Élie and his brother Daniel were brought up as Protestants under her strong moral influence and like Halévy's contemporary Max Weber, there was a strong familial influence on the study of religious – especially Christian Protestant – ideas. Though the family had important connections in French political life, Élie remained distant from, but also keenly concerned with, political affairs.

While still a student at the Lycée Condorcet, he planned with his brother and other associates, the *Révue de Métaphysique et de Morale*, a journal with which he was associated for the whole of his life. Celestin Bouglé collaborated on the *Révue* and later joined Émile Durkheim as editor of the *Année Sociologique*. Halévy entered the École Normale Supérieure in 1889, where he studied philosophy and completed a thesis on Platonism. The dialectical method he discerned in Plato was to form the analytical core of all his subsequent work. Already his political and moral principles had become established as liberal, individualist, rationalist, and secular – principles which were to characterize him for the rest of his career. He attributed these principles to the prevailing ethos of the École, which during his time as a student, was strongly liberal and *Dreyfusard*. In later life he mused that if he had attended the École 5 or 6 years later, he would have been a socialist. In 1898 Halévy became a professor at the École Libre des Sciences Politiques, which had been founded after France's defeat in 1871, with the goal of diagnosing the causes of French political instability; and he remained there all his professional life. He was initially appointed to teach a course of lectures on the evolution of political ideas in England but in the academic year 1901–02 he launched another course on the history of European socialism; and he alternated between the two for the following 35 years. The École Libre was much admired in Britain by the Fabians and their associates who founded the London School of Economics and Political Science; and Halévy came to know them well as he moved in British intellectual circles.

The Dreyfus affair and the defence of the Third Republic were issues which united Halévy with Émile Durkheim, though on a philosophical level he rejected Durkheim's positivism and collectivism. On the other hand, he attributed his initial interest in Socialism, to which he devoted half of his scholarly life, to Durkheim's lectures on Socialism at Bourdeaux in 1895. Another scholarly characteristic which Halévy and Durkheim shared was the remarkable continuity and consistency in their intellectual development. The affinity that Halévy perceived between Communist and Fascist régimes – since he viewed 1914 as the start of an 'era of tyrannies' – was an unpopular stance in the intellectual climate of the interwar years, but he persisted in his opinion until his death at Sucy-en-Brie in the Paris suburbs on 21 August 1937. The enthusiasm of the Webbs and Shaw for Fascist or Communist experiments in no way surprised him and he ended his life firmly committed to the liberal, rational, democratic ideals of his youth.

Intellectual Contributions

In his thesis, published in 1896 as *La théorie platonicienne des sciences*, Halévy explicated a dialectical approach, which he labeled Platonic, in which the contradictions in a subject were

stated as systematic dichotomies or antinomies. His objective was to systematize the seeming contradictions in Plato between what he termed the 'regressive dialectic' and the 'positive dialectic,' constructing from these his distinctive mode of analysis. Thus Halévy stated his aim as that of interpreting the dialectic "both as a critical method, with the purpose of destroying in us the illusion of science, and as a positive method, with the purpose of justifying all the sciences" (in Gillespie, 1950: p. 234; my translation). By exposing the core assumptions and practical implications behind a doctrine or belief system that usually involved logical conflicts, Halévy's own analysis of it could proceed. This fundamental principle of resolving contradictions into systematic dichotomies was deployed in his subsequent studies of Bentham's thought, Wesleyan doctrine and Socialism. His choice of England as the site of his first two areas of research was motivated by two main considerations: first, because it offered a striking location for the study of his central interest, the problem of liberty; and second, because the problematic relationship of ideas and beliefs to material circumstances in historical causality were clearly identifiable there.

In his study of the English Utilitarians he found a fundamental contradiction between Bentham's juridical and political theory on the one hand and economic theory on the other, and he argued that "the contradiction was continually breaking out in the current formulae of Benthamism" (Halévy, 1952: p. 489). In his political theory, Bentham postulated the necessity of a legislator who would reconcile conflicts of interest and thus secure the greatest good of the greatest number: this he called the artificial identity of interests. In his economic theory, however, Bentham assumed, with Adam Smith and his successors, that there was a spontaneous identity of interests and that individual interests were naturally harmonious. Halévy's book is a reminder that the Bentham who designed the *Panopticon* – "a new application of the principle of the artificial identification of interests, the idea of which he had found in Helvetius" (Halévy, 1952: p. 82) – also propagated a belief in laissez faire and the 'hidden hand.' Halévy suggests that because Bentham and his disciples focused on different aspects of their philosophy at different periods in its development, they were unaware of the contradictory dualism which underpinned their work. On the broader influence of the Utilitarians, Halévy argued that while they proposed no fundamentally new ideas – drawing on the ideas of Locke and their systematic development in French thought, particularly that of Montesquieu – their achievement lay in popular and practical agendas, which promoted free trade, legal reform, and the democratization of parliamentary government.

Soon after the completion of *The Growth of Philosophic Radicalism*, Halévy's interest turned to Methodism in eighteenth and nineteenth century England. Methodism was sometimes regarded as the complete antithesis of Utilitarianism, but Halévy regarded Methodism as an ally of Utilitarianism in shaping the social morality of modern England; indeed, he went on to argue that there was a strong affinity between Utilitarianism and Evangelicalism in the emphasis that both placed on self-restraint and self-discipline. In 1905 he traveled to England to work on material relating to the early history of Methodism and it was at this time that he expressed his intention of writing a history of England in the nineteenth century. His research on Methodism had a more immediate outcome, however, in two articles on 'La Naissance du Méthodisme en Angleterre' in the *Revue de Paris* in 1906. With very few exceptions these articles went unnoticed by historians until their translation into English in 1971 (Halévy, 1971).

The fundamentals of Halévy's interpretation of the role of Methodism in 'La Naissance…' correspond to his later treatment in *A History of the English People in 1815* (Halévy, 1924) – the first volume of his five-volume *A History of the English People*, which was published in French between 1912 and 1926 and in English between 1912 and 1932; however, the focus and detail of the earlier work provides a particularly strong statement of the 'Halévy thesis.' Since the thesis has become so indelibly associated with him, it is important to preface an account of it by noting that he was not the first to highlight Methodism's purported impact in averting revolution in England. Such an influence had been noted as early as the 1830s, and in 1878 William Lecky had published a particularly strong version of this interpretation in the second volume of his *History of England in the Eighteenth Century*. Halévy took as his point of departure the earliest development of manufacturing industry in the first three decades of the eighteenth century and pointed out the growth of pauperism in the industrial centers. By the late 1730s this was compounded by a commercial crisis of overproduction accompanied by working class agitation and it was this that stimulated the 'eruption,' in 1739, of Methodism. He argues that working class despair was transformed by Methodist doctrine and discipline into a religious and mystical movement of a conservative nature. In this process Halévy gave a key role to the bourgeoisie, a class that he saw as an essential component of leadership in harnessing the enthusiasm of the proletariat. Had the bourgeoisie in 1739 been fired by revolutionary ideals there might well have been conditions for social revolution; but the English bourgeoisie retained a strong element of Puritanism and a revulsion against the excesses of the seventeenth century Civil War. In Halévy's words, "There was the raw material for a general revolt. But popular discontent took the form the discontent of the bourgeoisie wanted to give it: a religious and conservative form" (Halévy, 1971: p. 75).

On this foundation is constructed the broader thesis with which Halévy is more generally known. At the outset it is noteworthy that his historical interpretation is specifically advanced as a critique of the materialist theory of history: "If the materialist theory of history is to be trusted, if economic facts explain the course taken by the human race in its progress, the England of the nineteenth century was surely, above all other countries, destined to revolution, both politically and religiously" (in Gillespie, 1950: p. 239). In *A History of the English People in 1815*, he stated the central problem as that of explaining "the extraordinary stability which English Society was destined to enjoy throughout a period of revolutions and crises; what we may truly term the miracle of modern England, anarchist but orderly, practical and businesslike, but religious, and even pietist" (Halévy, 1924: p. 339). The explanation he gives is complex and is not focused exclusively on Methodism nor solely on the working class. He traces the impact of Methodism first on Nonconformity, then on the Evangelical wing of the Church of England, and through them to the ruling class and finally to secular thought. In contrast to the view of religion as an 'opiate,' which Marxian critics of

Halévy such as E.P. Thompson have employed, the thesis is better interpreted as an exposition of upward social mobility through a process of *embourgeoisement*. Halévy did not attribute the influence of Methodism to the depths of the working class but saw it as having an impact on upwardly mobile workers: early in his *History* he refers to the "independent Churches of the lower middle class." Methodism, originating in the Church of England, occupied an interstitial position between that Church and Nonconformity, offering a means of passage between the two: "Puritan nonconformity thus tended to become a transitional creed, a stage in the history of an English family. The unskilled labourer becomes in turn a skilled workman, an artisan, the head of a small business, a business man possessed of a modest capital, and as he rises out of the barbarism in which the working class was plunged, he becomes a Nonconformist. If he himself rises still higher on the social ladder, or if his children rise after his death, he, or they go over to the Church of England" (Halévy, 1924: p. 371). Wesleyan Methodism, he claimed, rendered the transition imperceptible. Paradoxically, as the religious institutions facilitated such upward social mobility they also served to sharpen status distinctions; whereas the middle-class Nonconformist might have been despised by members of the Church of England (to which his family might one day belong), compensation for the precarious social position in which such upwardly mobile individuals found themselves could be identified in the contempt shown toward the working class from which the family had come. Hence Halévy's opinion that "the élite of the working class, the hard-working and capable bourgeois" had been instilled with values which did not threaten the existing order of society.

Wesleyan Methodism had originated in the Church of England among a group of conservative High Church clergy. In preaching an egalitarian doctrine of salvation for all, it had successfully mobilized an important segment of the rising working class. Here is an excellent example of Halévy's utilization of systematic dichotomy at the core of a belief system. He goes on to demonstrate the influence which Methodism had on establishment opinion by proposing that Wesley had left a 'rear-guard' in the Church of England in the form of the Evangelical movement, which sought to realize his original goal of church regeneration: "If the Wesleyan sect, with its hierarchic constitution, and frank political conservatism, constituted the High Church of Nonconformity, the new Low Church or evangelical party was a species of Anglican Methodism" (Halévy, 1924: p. 379). With powerful representatives at the University of Cambridge, and with wealthy and influential advocates in the 'Clapham sect' (which was comprised principally of Members of Parliament like William Wilberforce), the Evangelicals were in a position not only to influence ecclesiastical reform but also to campaign for a wider reform of morals – including the morals of the ruling class. In these several ways, argued Halévy, the influence of Wesleyan Methodism had permeated throughout English society and helped to establish the temper of Victorian England. The dominant features of English life in the nineteenth century were moral discipline, self-restraint, and the ethos of individualism which derived from Methodism and the wider Evangelical movement. Furthermore, Evangelical religion at the level of the individual, advocated philanthropy for the successful and resignation coupled with self-help for those who did not succeed. By contrast, no comparable institution, creed, or religious culture had developed in eighteenth century France.

Halévy's *Histoire du socialisme européen* (1948) and *L'ère des tyrannies* (1938) are the most cited of his works in France. The *Histoire* … was based on Halévy's own abundant lecture notes and those of some of his students. It was edited by Celestin Bouglé and Raymond Aron and has not been translated into English. *L'ère* appeared in English translation in 1966 as *The Era of Tyrannies: Essays on Socialism and War*. These works further extend the central theme of Halévy's work on English ideas, where the contrast between reform and revolution provided his comparative focus. Just as the contradiction between natural and artificial interests had been identified in Utilitarianism, and that between egalitarian salvation and hierarchical discipline in Wesleyanism, so the contradiction in socialism derived from the conjoint goals of human emancipation and the zeal to organize society. His history of socialism focused especially on the economic doctrine of Saint-Simon and his followers and a few years after he began his lectures on socialism he identified Saint-Simon as the pioneer or 'great precursor' of Socialism (Jones, 2002: p. 60) – a reminder that his grandfather Léon had succeeded Auguste Comte as Saint-Simon's secretary. The First World War was the decisive event in Halévy's view of Socialism, which was revised from a skeptical liberalism to a critical pessimism. The growth of the power of the state and the spread of bureaucracy were seen not only as threats to parliamentary democracy but also as evidence of the dominance of the organizational over the emancipatory principle in Socialism.

Halévy's central thesis is clearly stated: "Since its beginnings, in the early years of the nineteenth century, socialism has suffered from an internal contradiction. On the one hand, its partisans often present it as the outcome and fulfilment of the Revolution of 1789, a revolution of liberty, a liberation from the last remaining subjection after all the others have been destroyed: the subjection of labor by capital. But, on the other hand, it is also a reaction against individualism and liberalism; it proposes a new compulsory organization in place of the outworn institutions destroyed by the Revolution …" (Halévy, 1966: p. 265). It is known that the pessimistic conclusions he drew from this diagnosis surprised many in his intellectual circle at the Société Française de Philosophie and arrangements were being made for a further debate on his propositions, when he died in 1937.

Impact and Controversy

Halévy's work continues to be a focus of research and debate among social scientists. Two biographies have appeared, the first relating him to the French and European contexts of his time and the second emphasizing the major themes of his work: both characterize the 40-year span of his writing with the same term, 'unity' (Bramsen, 1978: p. 348; Chase, 1980: p. 3). In Chase's work there is a particularly clear exposition of the 'Halévy thesis' which gives effective treatment to aspects of his argument which have sometimes been obscured in subsequent debate, such as the broader significance of Nonconformity and his portrayal of the "hard-working and capable bourgeois" as the "élite of the working class." The republication in 1995 of

a French edition of his book on English Utilitarianism has stimulated critique of a work which had been widely accepted as a definitive analysis of its subject. Thus Halévy has been taken to task for allegedly interpreting the principle of utility or the pursuit of pleasure, as both a positive and a normative statement – as both an 'is' and an 'ought' (Vergara, 1998).

The parallels between Halévy and Max Weber are unmistakable. First, they are both associated with an eponymous 'thesis,' the core of which already existed as "the germ of a hypothesis" (Hill, 1973: p. 103). As indicated earlier, the claim that Methodism had been influential in preventing a revolution in England had been made as early as the 1830s. In a similar manner, the link between Protestantism and the rise of Capitalism which is enshrined in the 'Weber thesis,' had been proposed as early as 1829 by the poet Southey. Secondly, and more substantially, both adopted a comparative methodology in their accounts of the development of the modern state while retaining a sensitive awareness of the importance of historical contingency. A third equivalence in the work of Halévy and Weber can be found in their exploration of the link between ideal and material factors in the processes of social change. As Gillespie notes, Halévy's work "leaves the impression that the chief practical influence of ideas comes after they have hardened into dogmas and (though this makes the idealist interpretation of history a little difficult) that what often converts ideas into dogmas is their applicability to real interests in definite circumstances" (Gillespie, 1950: p. 236). This 'difficulty' is precisely what Weber addressed in his treatment of the dialectic between 'ideal' and 'material' interests associated with the twin concepts of 'elective affinity' and 'routinization.' Finally, the work of both scholars is characterized by a marked pessimism over the future progress of European societies, which they saw as destined to be subject to ever-encroaching bureaucratic control.

Halévy has exercised an enormous impact on the analysis of England's religious history and extensive attention has been paid to his claim that the Methodist and Evangelical movements were responsible for England's remarkable stability during a period of political ferment in Europe. Shortly after the publication of the first volume of *A History of the English People in the Nineteenth Century*, the Hammonds offered their portrayal of Methodism as having a repressive and intolerant stance toward the working class, and their interpretation questions Halévy's portrayal of its liberalizing influence on the exercise of judicial authority. In 1957 in *History Today* E.J. Hobsbawm took issue with Halévy's appraisal of the extent to which Methodism penetrated the working class and offered an alternative explanation that England's political stability was derived from the ability of the ruling class to retain control. E.P. Thompson's *The Making of the English Working Class* in 1963/1968, however, attributed even more influence to Methodism in subduing the working class than Halévy. Emphasizing the duality of Methodist emotionalism in worship and self-discipline in the workplace, he succinctly links Halévy with Weber when Thompson (1968: p. 406) notes: "Sabbath orgasms of feeling made more possible the single-minded weekday direction of those energies to the consummation of productive labour." Clark provides a reminder that Wesleyan Methodism was not a static movement when he states that "If the Methodism of the 1740s is to be understood in part as an Anglican exercise in social control, the evolution of Methodism in the direction of Dissent may have limited the movement's ability to provide an underpinning for society" (Clark, 2009: p. 22). Finally, in a 'Postscript on the Halévy Thesis' in *Victorian Minds*, Gertrude Himmelfarb (1968) commented on the curious status of this thesis in current historical literature. Whereas it has been often assumed that the thesis had been discredited or greatly modified, in reality there has been no substantial exploration of it. After reviewing the main features of the debate she concluded by paraphrasing Halévy: "Will Halévy defeat Marx as the interpreter of this crucial period in English history?" (Gertrude Himmelfarb, 1968: p. 299).

Himmelfarb's postscript became the preface to two decades of research into the 'Halévy thesis.' In 1971 Bernard Semmel's translation of Halévy's 1906 articles, *The Birth of Methodism in England*, was published with an introduction which noted that "the full dimensions of the thesis, as Halévy stated them, have been imperfectly understood" (Gertrude Himmelfarb, 1968: p. 2). This was because the 1906 articles had gone virtually unread. The thesis was further explored in *The Methodist Revolution* (Semmel, 1973), which began by noting that in major discussions of the 'Halévy thesis,' the role of Methodist theology had been afforded little significance, in contrast to social scientific discussions of seventeenth-century Calvinism. Semmel devoted several chapters to the elements which contributed to the synthesis of Methodist beliefs, restating Halévy's observation of an underlying contradiction between the revolutionary and counterrevolutionary elements of Wesleyan doctrine.

The thesis continued to be the subject of discussion throughout the 1970s and attracted the attention of sociologists examining religion and social change. In this context the 'Halévy thesis' has been described as "the political corollary, applied in a more restricted historical and geographical context, of the broader thesis put forward by Weber" (Hill, 1973: p. 183). As closer attention has been paid to Halévy's work, some of his specific historical observations – and their interpretation by more recent writers – have provided further stimulus for debate. One such area has been the role of foreign missions, and specifically of the Wesleyan Methodist Missionary Society. Did such activity provide a safety valve for social and religious tensions, rechanneling potentially disruptive enthusiasm by exporting it, or was there equal concern for home missions? These questions have been addressed in a revisiting of Halévy's original account (Piggin, 1980). Piggin challenges the 'Semmel thesis' which argued that foreign missions provided a mechanism of social control by rechanneling potentially disruptive evangelical enthusiasm, and especially Semmel's claim that the 'mission party' within Wesleyan Methodism "deliberately redirected resources and energies into the safe and enervating task of converting the rest of the world" (Piggin, 1980: p. 18). Instead, he thinks, foreign missions revitalized the home churches and made available enhanced resources for home missions.

In a wide-ranging review of the debate, Itzkin (like Himmelfarb before her) has noted that many of the contentious issues remain unresolved. While Halévy's antagonists have succeeded in revising some of his claims, the central thesis has remained viable and continues to constitute a 'working historical hypothesis' (Itzkin, 1975: p. 56). In the work of

revision, attention has focused on the numerical strength of Methodism together with its geographical distribution; on the nature and political stances of the variety of bodies which came within the overall rubric of Methodism; and on the way in which moderate political deviance can make "an important contribution to public order and political stability" (Gilbert, 1979: p. 392).

With the culmination of two decades of lively debate over the 'Halévy thesis' a collection of most of the important statements was published in Olsen (1990). Extracts from Halévy, from historians of Methodism and Evangelicalism such as Maldwyn Edwards, John Walsh, and Kiernan, and from critics like the Hammonds, Hobsbawm, and Thompson, provide a striking testimony to the continuing vitality of a thesis first advanced in 1906. As has been indicated, the parallel with the 'Weber thesis,' first published in 1904–05, is too close to ignore.

Halévy's lectures on the history of Socialism, reconstructed from his students' notes and published posthumously as *Histoire du Socialisme Européen* in 1948, remains untranslated into English. *The Era of Tyrannies*, first published posthumously in French in 1938, has however been translated and published in English (Halévy, 1966). After its first publication in France, his argument stimulated interest among those with whom Halévy maintained links at the London School of Economics, including Freidrich Hayek, who was editor of the LSE house magazine *Economica* in which Halévy's piece was republished. It has been suggested that his influence is identifiable in Hayek's *The Counter-Revolution of Science* and *The Road to Serfdom*, both of which date from the same period in the early 1940s (Jones, 2002). In *The Era of Tyrannies* the author provides not only a summary account of socialism but also a treatment of the 'era of tyrannies' – using the term in the classical Greek sense of a group of armed men who seize the state – under Stalin, Hitler, and Mussolini. At the end of World War I Halévy had written: "…I recognize that socialism holds the key to the secret of the future. But I cannot decipher this secret nor can I say whether socialism will lead us to a Swiss-type, universalized Republic or to European Caesarism" (in Aron, 1984: p. 407). Halévy's emphasis on the concrete influence of World War I rather than the influences of Marxism or other collectivist doctrines in the advance of socialism has been seen as qualifying somewhat his otherwise idealist interpretation of historical change.

In the last years of his life Halévy took an increasingly pessimistic view of Europe's future in the event of another war, which he thought likely. For him, this would represent the final blow to liberal traditions; but for this judgment Aron has criticized him. While cautioning against overconfidence, Aron thought Halévy had "sinned through over-pessimism" (Aron, 1984: p. 422). With the benefit of hindsight Aron's criticism may be justified, but it should be recalled that in the era of the 1930s Halévy was not alone among social scientists who believed that the capitalist élite were becoming 'highly placed bureaucrats.'

Abstract

Granville Stanley Hall's (1844–1924) lifetime intellectual accomplishment was the creation of the American discipline of psychology and the science of education out of the then broader study of philosophy. He developed these academic specializations through his long faculty and presidential career, numerous books, and more than 400 other publications, creation of several research journals, and extensive professional conference presentations. Accordingly, after earning the first American doctorate in psychology from Harvard in 1878, a brilliant academic career followed. Hall began as a lecturer in philosophy at the new Johns Hopkins University that led to his first appointed position there as professor of psychology and pedagogics in 1884. He established the *American Journal of Psychology* there in 1887. The following year, Hall became president of research-oriented Clark University where he continued his professional and scholarly activities. In 1892, Hall founded the American Psychological Association. He then furthered the scientific study of education through his lectures and became the national leader of the American child study movement. To promote such research, the president created the educational research journal, *The Pedagogical Seminary*. Through these and other activities, Hall played the initial pivotal and defining role in founding psychology and education as social and behavioral sciences in American higher education.

The age of the modern research university began with the founding of the Humboldt University in Berlin in 1810. One of the 9000 Americans who studied at this and other German universities during the nineteenth century was Granville Stanley Hall. He, like they, sought to gain more advanced knowledge and research skills than was available elsewhere. This educational opportunity aided him in becoming the first professor of psychology and pedagogics at the new Johns Hopkins University, and later the first president of research-oriented at Clark University in the USA. During his academic career, Hall launched the American discipline of psychology (Ross, 1972, 1979) and the science of education (White, 1992), out of the then broader study of philosophy. He achieved these intellectual accomplishments through his long faculty and presidential career, numerous books and more than 400 other publications, creation of research journals, and extensive professional conference presentations. In this way, Hall played the initial pivotal and defining role in founding psychology and education as social and behavioral sciences in American higher education (Mitchell and Haro, 1999, p. 50; Lagemann, 2000).

Hall's Early Life, Career, and Intellectual Pursuits Until 1880

Born in Ashfield, Massachusetts on 1 February 1844 to Granville Bascom Hall and Abigail Beals Hall, Stanley was the oldest of nine siblings. His upbringing on the family farm offered his inquisitive mind opportunities to observe nature intimately, which would so powerfully shape his future intellectual outlook. Eschewing agrarian life, Hall completed college preparatory studies at Williston Seminary in Easthampton, Massachusetts in 1862 and entered Williams College in the following year. There he studied under two famous American educators and philosophers, Mark Hopkins and John Bascom. Their influences shaped his interest in philosophy and theology, respectively. Finishing his bachelor's degree in 1867, Hall next decided to study for the ministry and entered Union Theological Seminary in New York. Yet, two years of study, some pastoral experience, and a frank discussion about his intellectual interests with the imposing American theologian Henry Ward Beecher resulted in Hall's first trip to Germany to study philosophy at the University of Berlin in 1869. In Friedrich Adolf Trendelenburg's seminary, he became an avowed Hegelian and contemplated becoming a philosopher. With the outbreak of the Frank-Prussian war, Hall returned to New York and finished his bachelor's degree in divinity in 1871. Yet, his intellectual and philosophy study there led him to embrace the evolutionary ideas of Charles Darwin and Herbert Spencer (Hall, 1923).

Forsaking the ministry then, Hall sought the academic life. He became a professor at Antioch College in Ohio, where he taught English, French, and German from 1872 to 1876. Becoming increasingly disenchanted with Hegel intellectually during this time, Hall openly became an enthusiast for Darwin, Spencer, and Huxley and positivistic science (Hall, 1923, p. 199, Ross, 1972, pp. 58–59). The turning point in his intellectual life occurred with his reading of Wilhelm Wundt's (1873) first volume of *Physiological Psychology*, after which he decided to specialize in psychology. Leaving Antioch, Hall completed a Ph.D at Harvard University in 1878 under William James; it was the first doctorate in psychology awarded in the USA. His dissertation explored the physiological relationships between muscles, nerves, and consciousness from a genetic perspective (Ross, 1972, pp. 70–75; Wilson, 1914, p. 64). Hall's research showed his fascination with experimental psychology and its links to Darwinian and Spencerian evolutionary thought. To bolster his research in the study of psychology, and because he could not obtain a suitable professorial appointment at a major university, Hall again went to Germany to study under Hermann von Helmholtz and William Wundt at the universities of Berlin and Leipzig, respectively (Goodchild, 1996, pp. 72–73).

Hall's Faculty Appointments at Johns Hopkins University from 1882 to 1887

After returning to the USA in 1880, Hall lectured at Harvard at the invitation of President Charles W. Eliot and then at

Hopkins by courtesy of President Daniel Coit Gilman. Later the Hopkins president appointed him a lecturer in 1882 and then Professor of Psychology and Pedagogics in 1884. From these positions, Hall furthered the study of education and psychology through a series of major articles exploring their relationships to human development. First, he surveyed pedagogical study in the USA and then explored the moral and religious training of both children and adolescents in one of his first discussions of child development. In analyzing the needs of education later, the professor stated boldly that 'we must study and follow the child's nature as it actually is' (Hall, 1883a, p. 286). Hall further proclaimed his new concept of 'natural' methods of education where education and psychology may both be utilized to understand the relationship between intelligence and human development in his important article, New Departures in Education (Hall, 1885a, pp. 147–148). Finally, he and one of his doctoral students outlined the entire field of education in their 1886 book, *Bibliography of Education* (Hall and Mansfield, 1886).

Second, in psychology, Hall quickly created one of the first experimental psychological laboratories in America at Hopkins and authored many of its early articles in experimental psychology (Boring, 1950; Hawkins, 1960, pp. 202–203). One of his important contributions was the publication of 'The new psychology' (1885b) which outlined this developing field. In 1887, he created a new research journal, the *American Journal of Psychology*, to publish psychological research. It was pivotal in establishing this new discipline. Third, his pedagogical and psychological ideas had already coalesced a few years earlier in his first major empirical studies using questionnaires on child development. 'The contents of children's minds' (1883b) and *The Study of Children* (1883c) described 'the real nature' of children, used the reports of actual teachers' observations from the questionnaires, and suggested appropriate pedagogical techniques. They played a major role in launching Hall's national reputation and his central position as the founder of the child study movement in the USA (White, 1990). Some of his doctoral students followed him as his career evolved; others, particularly John Dewey and James McKeen Cattell, were not favored and moved onto their own significant accomplishments (Ross, 1972, pp. 144–147). Thus Hall's work at Hopkins set the stage for the remainder of his scholarly career and publications as he pursued research in education, psychology, and their mutual implications for understanding human development.

Hall's Presidency of Clark University from 1888 to 1920

In Worcester, Massachusetts, wealthy industrialist Jonas Clark founded an institution of higher learning with a $1 million gift in 1887. He intended it to have a research mission for older male students and be a 'useful' college for local boys(Koelsch, 1987, pp. 9–12). Hall was named its first president in April 1888. He was determined to create a new graduate research university comparable to Hopkins, following the German ideal. The first three years saw considerable fulfillment of his vision. However, conflict with the founder over the college and loss of many faculty members to the new University of Chicago severely constrained the president. The struggling and much smaller institution still embraced the primacy of research as the reform ideal for the mission of all American universities (Goodchild, 1996; Goodchild and Miller, 1997). Eventually, Hall allowed an undergraduate college to be created when funds from the founder's estate became available. The president remained highly productive in his research and continued to oversee the institution until his retirement in 1920.

Hall's Prolific Scholarly Achievements during his Presidency

The president's accomplishments in psychology, education, and their implications for a new genetic interpretation of human development established the American prominence of these new scientific fields of study. In psychology, Hall founded the American Psychological Association in 1892, became its first president, and anchored his *American Journal of Psychology* to the organization. It remained the pre-eminent national association for this growing academic discipline. In 1904, Hall's most famous psychological study, *Adolescence: Its Psychology and Its Relations to Physiology, Anthropology, Sociology, Sex, Crime, Religion and Education*, appeared. This definitive two-volume work on adolescence comprised many of his earlier ideas on the child's next stage of development, established this stage as a scientific concept, related this developmental period to various human behaviors, and discussed its meaning for other emerging academic fields, especially education. Hall's interest in the sexual development of youth in this work was ground breaking. It led him to invite Sigmund Freud, Carl Jung, and many other leading psychologists to the famous 1909 twentieth Anniversary Conference of the founding of Clark University (Koelsch, 1987, pp. 246–247). As if to secure his role in this developing discipline, Hall published the valuable book, *Founders of Modern Psychology*, in 1912. After World War I, the scholarly president turned to his lifelong interest in religion and its psychological meaning. He authored a major reinterpretation of Christianity's founder in his *Jesus the Christ, in the Light of Psychology* (1917) and its application in the advocacy of a new life ethic in his *Morale: The Supreme Standard of Life and Conduct* (1920a) in which Hall espoused a holistic understanding of health and well-being as the rule for human conduct. With retirement from Clark's presidency in 1920, Hall reflected on his accomplishments in his *Recreations of a Psychologist* (1920b), and *Life and Confessions of a Psychologist* (1923). Hall achieved another scholarly triumph by completing his work on the last stage of human development with the publication of *Senescence: The Last Half of Life* (1922). In all this pioneering work, he made some significant missteps, especially claiming child development recapitulates human evolution (White, 1990, p. 31) and a too pervasive Darwinian and Spencerian 'evolutionism' (Ross, 1972, p. 92). On the other hand, he awarded the first doctorate in psychology to an African-American and encouraged Asian students to study psychology at Clark (Goodchild, 1996).

By his death on 24 April 1924, Hall had established psychology as an American discipline and study, almost entirely graduated the next generation of psychologists (Goodchild and Miller, 1997), and secured the role of behavioral and genetic psychology as being an integral part. To insure the

continuation of his work, Hall's estate established at Clark an endowment for a genetic psychology professorship and for his educational journal that was redirected and renamed *The Journal of Genetic Psychology*.

Similarly, his work in education commanded national attention. Hall believed that education was applied psychology. He followed identical approaches in establishing the importance of education as a field of study, as he had done in psychology. Hall offered a series of university lectures on kindergarten, elementary, secondary, and higher education (Goodchild, 1991). He next founded a research journal, *The Pedagogical Seminary: An International Record of Educational Literature, Institutions, and Progress,* in 1891. It provided a new research outlet from studies intended to reform education from American and international perspectives. Further, he extracted his pedagogical ideas from his books on adolescence and released them as *Youth: Its Education, Regimen, and Hygiene* (1906) to serve educators and teachers who were implementing his ideas in the classroom. Five years later, Hall presented his definitive study on education with another extensive two-volume work, *Educational Problems* (1911). He claimed to have fomented an American educational revolution where 'now the school, including its buildings, all its matter and method, revolve about the child' (p. 1: vi). This 'natural' education was to be individualized to the student's developmental stage, sex, and race. Thus pedagogy was to assist in the intellectual development of every person, although higher education was intended for the most able. At Clark, Hall had been instrumental in creating the study of education – particularly in conducting empirical research on children to develop better pedagogy, offering the first courses in higher education, and espousing genetic psychology as the basis for educational practice. His extensive publications in higher education focused on the mission of the new research university and its faculty (Goodchild, 1996). Similarly, missteps occurred in education as Hall advocated separate education for women, decried 'identical' coeducation, and espoused elitism in higher education (Ross, 1972, pp. 311–312). Nevertheless, the president greatly assisted in the arrival of education as an academic field of study (Cremin, 1961).

Hall's most significant contribution may be the creation of developmental psychology and its relationship to education (White, 1992). His research on child study, adolescence, and old age enabled him to argue for five stages of human development: (1) childhood; (2) adolescence; (3) middle life, from 25 to 45; (4) senescence, after 40; and (5) senectitude, approximately near the end of life (Hall, 1922, p. vii). His psychological and educational ideas and practices were focused on what he believed, would further the human race. His Darwinian and Spencerian concepts of evolution pervaded his understanding of human genetic development. He consistently maintained these ideals, even in the face of demands for coeducation in schools, growing behaviorism in psychology, and expansive progressivism in education. Hall was a man of his times, his scientific worldview centered on the mid- to late nineteenth century ideas and their implications for professional practice.

Finally, Hall's most important achievement when assessing the rise of the social and behavioral sciences was to engender the development of psychology and education from their philosophical progenitor. His patterns consisted of a critical assessment of the condition of the field first, next an assertion of a new position for the field, then a new research journal to publish these findings, and finally definitive works exploring the field of study. Hall thus played an essential role in the establishment of psychology and education as new academic fields of study in the USA. In 1992, the centenary meeting of the American

Psychological Association pointed to his pivotal role in these founding moments (Goodchild, 1992; White, 1992).

Abstract

Hallucinations are perceptions that occur in the absence of external stimuli, and have sufficient realistic quality to resemble actual perception of external phenomena. This article presents an overview of several proposed neural mechanisms for the production of hallucinations, such as deafferentation, release theory, misinterpretations of internal input, and deficits in top-down processing. The most common types of hallucinations are reviewed in detail (i.e., visual and auditory phenomena). Hallucinogenic drugs, such as lysergic acid diethylamide, mescaline, and psilocybin, are known to produce visual and auditory distortions; however, withdrawal from certain pharmacological substances may also produce hallucinations. Psychiatric illnesses and the associated hallucinatory phenomena are also discussed.

Hallucinations are perceptions that occur in the absence of external stimuli, and have sufficient realistic quality to resemble actual perception of external phenomena. These perceptions are not under voluntary control. Hallucinations can occur in any sensory modality, and differ from delusions. Although hallucinations occur in various psychiatric conditions, around 6% of the general population reported having hallucinations at least once a month (Ohayon, 2000). The phenomenon can be distinguished from that of *illusions*, which are misinterpretations of stimuli that are actually present. Gilles Fénelon (2013) categorizes the mechanisms of hallucinations into four groups. The hallucinations occurring in epilepsy and migraines result from spontaneous overactivation in sensory areas. Deafferentation (the loss or destruction of sensory input) facilitates hallucinatory experiences by leading to a chronic hyperexcitable state in cortical areas. A third mechanism is attributed to the dissociation of the dream and sleep state. Lastly, hallucinations can arise from dysfunction in bottom-up processing and top-down mechanisms. *Pseudo-hallucinations* refer to hallucinations with preserved insight, or the knowledge that one is hallucinating (Fénelon, 2013: 59). The major types of visual hallucinations are described below.

Visual Hallucinations

Elementary visual hallucinations are more common than complex shapes and human figures (Billock and Tsou, 2012). There are three types of elementary hallucinations. *Phosphenes* are the simplest form, and consist of small spots of light. *Geometric figures* are the second type, and consist of lattices, pinwheels, and spiral images. *Fortifications* are bright flashing arc patterns that may appear zigzagged (Billock and Tsou, 2012). Complex hallucinations consist of images such as objects, people, and landscapes. During *palinopsia*, an image remains in view after the perceived stimulus is no longer present. The colors of these persistent images can be the same as the original stimulus, inverted, or can appear to have 'trails.' Palinopsia has been localized in the parietal projections to the occipital cortex (Smith et al., 2003). A person is aware that visual hallucinations are not real during *peduncular hallucinosis*, which consists of brief, vivid, colorful representations of geometric patterns, people, animals, and scenes. These hallucinations do not have symbolic significance and are not associated with delusional thinking. They have commonly been associated with lesions in the midbrain and the reticular formation (Parisis et al., 2003). *Hypnagogic* hallucinations occur during the wake–sleep phase, whereas *hypnopompic* hallucinations occur during the sleep–wake phase; both are frequent in nonclinical populations (Fénelon, 2013: 59). These hallucinations have been associated with attentional biases occurring in the anterior cingulate gyrus (Fénelon, 2013: 59). Body misperceptions may consist of both out-of-body experiences and *autoscopic* hallucinations. Autoscopic hallucinations involve seeing an image of one's self in external space from his or her physical point of view. Out-of-body experiences have been associated with the right temporo-parietal cortex, whereas autoscopic hallucinations are associated with both temporo-occipital cortices. *Heautoscopy* refers to seeing a double of oneself in external space, but having difficulty differentiating in which body the self is situated (Fénelon, 2013: 59). *Heautoscopy* has been associated with the left temporo-parietal cortex.

Charles Bonnet syndrome (CBS) refers to visual hallucinations that occur throughout the course of an eye disease; these visual hallucinations include palinopsia (the appearance of a trailing object) and *polyopia*, in which a stimulus becomes multiplied (Ffytche and Howard, 1999). Elementary hallucinations are more common, but complex visual hallucinations can include people, animals, and complex scenes. Interestingly, visual hallucinations reported by persons with CBS include *lilliputian figures*, or small, doll-like people (Ffytche, 2007). Although the type of eye disease is not relevant, the amount of cognitive impairment appears to contribute to the presence of visual hallucinations. Traditionally, postulated neural mechanisms for Charles Bonnet syndrome are that a loss of visual stimuli leads to cortical inhibition, which creates visual hallucinations. More recent theories by Burke (2002) stress the importance of the molecular changes that take place in deafferented neurons which create the bursts of activity, not necessarily an interruption of inhibitory processes.

Auditory Hallucinations

Auditory hallucinations can be simple sounds (e.g., knocks, rings, and tinnitus), or can consist of complex sounds, such as music or voices. When these hallucinations occur outside of schizophrenia, they are rarely threatening or shaming in nature (Fénelon, 2013: 59). Auditory hallucinations can vary in location (coming from inside or outside of the head), voice familiarity, loudness, and content (Stephane, 2013). Analogous to visual hallucinations, auditory hallucinations may arise from an impairment in hearing. Hallucinations associated with hearing impairment are typically elementary sounds, such as tinnitus, but may also be voices or music (Cole et al., 2002). The musical hallucinations that occur in deaf individuals are considered to be an equivalent of the visual hallucinations reported in CBS. Musical hallucinations are usually reported in acquired deafness, but have also been associated with depression, obsessive–compulsive disorder, schizophrenia, and lesions in the brainstem or cerebral hemispheres (Stewart et al., 2006). The physiology of auditory hallucinations associated with deafness is less clear; PET scans have indicated that the same neural networks are activated during hallucinations as in normal musical perception (Stewart et al., 2006).

A number of variables are associated with different neural bases for auditory hallucinations, such as *anosognosia* (lack of awareness of the hallucination), content, spatial location of the hallucination (inside or outside of the head), and voice familiarity. Anosognosia is associated with lesions of the frontal lobes, the visual associative cortex, and specific neural substrates (Stephane, 2013). The right temporoparietal junction has been associated with the spatial location of hallucinations (Plaze et al., 2011). Larøi and Woodward (2007) have theorized that auditory hallucinations may result from deficits in understanding the boundaries between self–other and inner space–outer space. Stephane et al. (2006) has found that abnormal laterality in motor areas of the brain may be attributable to the failure to discriminate whether speech was generated internally or externally. Activation in Wernicke's area may also account for the actual perception of auditory hallucinations (Stephane et al., 2006).

Hallucinations in Other Sensory Modalities

Although they are less common than auditory and visual hallucinations, hallucinations can consist of olfactory, gustatory, and somatosensory content. Olfactory hallucinations are usually reported during temporal lobe seizures or migraine auras, typically as a result of damage to the olfactory bulb. The smells usually comprise unpleasant odors, such as the smell of burning material, decaying flesh, or other rancid odors, although smells of perfume, flowers, and food have also been reported (Stevenson et al., 2011). Olfactory hallucinations have been noted more often in late-onset schizophrenia, and may influence delusional beliefs that the schizophrenic individual smells of the foul odor (Hoffman, 2003). Interestingly, olfactory hallucinations are not well explained by theories of visual and auditory hallucinations. Visual and auditory phenomena are explained by misattributions of internal versus external world phenomena due to impairment in attentional and metacognitive processing (Bentall, 1990). The same theory does not apply to olfactory hallucinations; it is difficult to imagine forming a mental image of a certain smell and misattributing it to an external stimulus (Stevenson et al., 2011).

Tactile hallucinations may consist of sensations that one's skin is crawling with insects, that is, *formication*. The phantom-limb hallucination, or the feeling that an amputated limb is still intact (and possibly painful), is a common somatosensory hallucination following surgery, although the experience of phantom-limb pain may occur years after amputation. Gustatory hallucinations have been reported in patients experiencing mood disorders, drug ingestion, and sleep deprivation (Ohayon, 2000). The experience of olfactory and gustatory hallucinations occurs as often together as they do separately (Lewandowski et al., 2009). Similar to olfactory hallucinations, gustatory hallucinations typically involve the sensation of tasting something unpleasant.

Psychiatric Illnesses Associated with Hallucinations

Elementary hallucinations are more commonly associated with the effects of migraine auras, epilepsy, hypoglycemia, and eye diseases (e.g., CBS). Complex hallucinations are more common in partial epilepsy, Parkinson's disease, Alzheimer's disease, and dementia with Lewy bodies (DLB) (Fénelon, 2013: 59). Hallucinations are generally associated with the positive symptoms of *schizophrenia*. Auditory hallucinations associated with schizophrenia are often voices, and may contain shaming or derogatory content. The hallucinations may vary from single words to complex sentences, although single words are reported more frequently (Larøi et al., 2012). These voices can sound familiar to the way other voices sound, or may be perceived as unreal (Larøi et al., 2012). Some individuals may find it difficult to differentiate whether the voice is coming from within the head or outside of the body. Functional connectivity studies of auditory hallucinations in schizophrenic populations suggest that the mechanism involves a complex pathway between Wernicke's area, the left inferior frontal cortex, and the putamen (Hoffman and Hampson, 2012). Interestingly, the putamen is involved both in determining whether auditory stimuli are consciously perceived and in the production of spontaneous language (Hoffman and Hampson, 2012). While functional neuroimaging studies report different activation areas, it has generally been found that speech generation and perception areas in both the left hemisphere and their corresponding right hemisphere are involved. The initiation of such hallucinations is theorized to be attributed to activity in the parahippocampal gyrus (Aleman and Vercammen, 2012: 267). Visual hallucinations in schizophrenic patients are associated with increased hippocampal activity (Larøi et al., 2012).

In partial *epilepsy*, the following hallucinations are most common, in decreasing order of prevalence: complex visual, somatosensory, auditory, gustatory, and olfactory hallucinations (Mauguiére, 1999). Autoscopic visual hallucinations and out-of-body experiences are often reported in epilepsy. The majority of hallucinations associated with occipital lobe epilepsy are elementary hallucinations, such as rotating lights

or flashing colors (Bauer and Hamer, 2012: 241). Complex visual hallucinations have also been reported, consisting of seeing people, objects, or some visual alteration of one's environment (Guimond et al., 2009). Hallucinations reported in parietal lobe epilepsy include both elementary and complex visual content. Temporal lobe seizures, on the other hand, have typically been associated with gustatory and olfactory hallucinations as well as with visual hallucinations. Phosphenes, sparks, and other simple visual hallucinations are reported in patients who have experienced occipital lobe seizures (Lhatoo and Sander, 2003: 207). Ictal auditory hallucinations are both simple and complex; simple hallucinations have been associated with activity in the primary auditory cortex (Fénelon, 2013: 59). It has been shown that patients experiencing verbal auditory hallucinations have greater left-hemispheric activation, whereas nonverbal auditory ictal hallucinations have more right-hemispheric activation. This has been demonstrated regardless of whether the hallucinations are heard in one or both ears (Guimond et al., 2009). Hallucinations experienced may be a combination of more than one sensory modality; however, olfactory and gustatory sensations are not common (Fénelon, 2013: 59).

A 'classic migraine' is accompanied by an *aura*, which is a term for the accompanying neurological symptoms that either precede or appear congruently with the migraine attack (Silberstein, 2003: 174). To meet criteria for a classic migraine, an individual must experience a migraine during an aura or within 60 min after the aura has begun; in addition, reversible visual distortions or hallucinations are present. Elementary hallucinations are more common in migraine auras, followed by somatosensory hallucinations (Pietrobon and Striessnig, 2003). Common elementary hallucinations include geometric patterns, phosphenes, and fortifications (Billock and Tsou, 2012). Complex visual distortions may include Alice in Wonderland-like perceptions (more frequently seen in children), and *teichopsia* (an arc of light that appears as a zigzag pattern, similar to the appearance of fortifications seen on castles) (Silberstein, 2003: 174). Olfactory hallucinations are also a common aura symptom. Compared with epileptic seizures, which only last several seconds, aura symptoms may last for many minutes. The length of hallucinatory experiences provides valuable differential diagnostic information between epilepsy and migraines (Billock and Tsou, 2012).

In *Parkinson's disease*, the following hallucinations are most common, in decreasing order of prevalence: complex visual, auditory, tactile, and olfactory hallucinations (Fénelon et al., 2011). Complex hallucinations consist of people, objects, or animals; they typically last for only seconds, are usually superimposed onto the actual environment, and may be relatively stereotyped for the individual (Fénelon, 2013: 59). In the majority of cases, auditory hallucinations are heard externally and do not contain affective components or derogatory content. When multimodal hallucinations are present (e.g., both auditory and visual hallucinations), there is typically no relationship between their content (Inzelberg et al., 1998). Models of hallucinations in Parkinson's disease comprise deficits in both bottom-up and top-down processing of sensory information, as well as intrusions of internal phenomena (e.g., dreams) during consciousness (Fénelon, 2013: 59). It has been speculated that some hallucinations associated with Lewy body disorders may result from dissociation between the dream and the wake state, or the intrusion of internal phenomena misinterpreted as external stimuli (Fénelon, 2013: 59). Hallucinations typically occur several years after onset of Parkinson's disease.

In *DLB*, the following hallucinations are most common, in decreasing order of prevalence: complex visual, auditory, tactile, and olfactory hallucinations (McKeith, 2002). The diagnosis of DLB is based upon the presence of Lewy bodies, which are intracellular hyaline inclusions that are found in some patients suffering from Parkinson's disease (Goral et al., 2006: 16). Lewy bodies are found in cortical and subcortical regions of the brain. Characteristics of DLB include a decline in cognitive functioning, visual hallucinations, and spontaneous parkinsonism (Goral et al., 2006: 16). Hallucinations associated with DLB are similar to those observed in Parkinson's disease, although they typically have a shorter timecourse for onset (Fénelon, 2013: 59). Recurrent visual hallucinations in both DLB and Parkinson's disease tend to be complex rather than elementary; this may reflect a mechanism of hallucinations that is disease dependent and affected by cortical areas, specifically the dorsal and ventral pathways (Mosimann et al., 2006). Visual hallucinations are more complex in DLB than that experienced in Alzheimer's disease; the complexity provides a useful diagnostic distinction between the two (Swanberg and Cummings, 2003: 207). The hallucinations are more vivid and contain complex images of objects, animals, or people that are normal in size (Swanberg and Cummings, 2003: 207). In *Alzheimer's disease*, the following hallucinations are most common, in decreasing order of prevalence: complex visual, auditory, tactile, and olfactory hallucinations (Ropacki and Jeste, 2005). Visual hallucinations typically include people, animals, and objects. Auditory hallucinations are less common, and olfactory hallucinations are quite rare (Fénelon, 2013: 59). Delusions and hallucinations, especially visual hallucinations, have been shown to be related to greater cognitive impairment and rates of cognitive decline in Alzheimer's patients (Wilson et al., 2006). The supposed mechanisms are still speculative, but it is theorized that hallucinations in dementia of the Alzheimer's type result from deficits in top-down processing and visual sensory processing (Fénelon, 2013: 59).

Diagnostic criteria for *delirium* include a disturbance in consciousness that is accompanied by several cognitive impairments; delusions and hallucinations are also common. Visual hallucinations are most commonly reported, followed by auditory and somatosensory misperceptions (Folstein and Caplan, 2003: 207). Severe *mood disorders*, such as a major depression, can be accompanied by hallucinations. Auditory misperceptions are the most commonly reported hallucination, with single words and short phrases heard. Patients with bipolar disorder may experience hallucinations that contain both verbal and nonverbal auditory contents; these hallucinations may be inconsistent throughout mood phases (Larøi and Woodward, 2007). These hallucinations are often accompanied by delusions and may contain themes of grandiosity, a hallmark symptom of a manic episode. The prevalence of hallucinations in the context of *borderline personality disorder* is less clear; it is suggested that the hallucinations are short lasting compared to schizophrenic hallucinations, and are often

perceived as coming from within one's head, but out of one's control (Larøi and Woodward, 2007).

Pharmacology of Hallucinations; Drug-Induced States

Hallucinogenic drugs, or psychedelics, are chemicals that produce the psychotic experiences of hallucinations, alterations in cognition, and grandiosity or paranoia (Goetz, 2003: 174). The user experiences misperceptions that arise from the dissociation between internal and external phenomena. The most common hallucinogen in the United States is *lysergic acid diethylamide* (LSD), which produces powerful effects that may persist for several hours. Initial feelings of grandiosity and pleasure may be replaced by feelings of anxiety or panic as the drug's effect progresses. Hallucinations associated with LSD include reports of intense, vivid colors, and elementary hallucinations (Goetz, 2003: 174). In general, effects caused by hallucinogens are more likely to be visual misperceptions, although auditory tactile hallucinations have been reported (Larøi and Woodward, 2007). Mescaline (peyote cactus) and psilocybin (mushrooms) are hallucinogens that have been used as part of Native American religious ceremonies (Goetz, 2003: 174).

Cocaine, cyclic antidepressants, cannabis (tetrahydrocannabinol, THC), MDMA (methylenedioxymethamphetamine), carbamazepine, and salicylates have been known to produce hallucinatory experiences (Von Rosen and Brust, 2003: 207). In high doses, anticholinergic drugs may cause hallucinations and delirium, which may be misattributed to the presence of a psychiatric disorder (Fann, 2006: 354). Hallucinations may also be triggered by withdrawal from substances. Patients with chronic alcoholism may experience hallucinations during withdrawal (Hoffman, 2003: 500). Withdrawal from cocaine, amphetamines, cannabis, and LSD may also be accompanied by hallucinations (Larøi and Woodward, 2007). Feelings of formication (i.e., the sensation of one's skin crawling with insects) have been associated with withdrawal from alcohol, amphetamine, and cocaine (Larøi and Woodward, 2007).

Proposed Mechanisms of Hallucinations

The remainder of the article serves as an overview of the different neural mechanisms of hallucinations. Hallucinations associated with seizures or migraines with auras are assumed to be the product of overactivation that spontaneously results in sensory cortical areas (Fénelon, 2013: 59). *Ictal* hallucinations refer to hallucinations that occur during an aura or partial epilepsy; however, the same effect can be achieved by cortical stimulation. For example, stimulation of the V1 area of the cortex has been known to produce simple visual hallucinations in the form of colored phosphenes; stimulation outside of this area leads to the experience of colorless phosphenes (Billock and Tsou, 2012). In addition, the type of psychological hallucination has been shown to be dependent on which hemisphere is activated. It is theorized that ictal hallucinations are caused by an activation of brain tissue near that area; as such, ictal phenomena may provide a route to further examine hemispheric specialization (Guimond et al., 2009).

Deafferentation, also known as the loss/disruption of sensory input, may also produce hallucinations. Deafferentation in any sensory modality has the ability to facilitate hallucinations in that sense (Fénelon, 2013: 59). This type of mechanism produces the hallucinations seen in CBS and, more classically, phantom-limb phenomena. When a limb is amputated, it is usually followed by a feeling that the limb is still intact, a sensation known as 'phantom-limb awareness'; this sensation is reported by almost all amputees (Flor et al., 2006). The sensation may be rare and short lived, or may be a chronic sensation of pain during which the individual perceives the missing limb. It is theorized that phantom limb sensations are experienced due to a restructuring of somatosensory maps in the cortex (Flor et al., 2006).

When a region of the brain is deafferented, the cells within this region are more excitable; this can occur in any region associated with sensory perception. The deafferentated neurons undergo biological changes that cause hyperexcitability (Burke, 2002). These neurons experience periods of inactivity interspersed with bursts of excitability that resemble seizures (Burke, 2002). The *release* theory of hallucinations by West (1962) states that hallucinations arise due to an impairment of a sensory modality or its connecting pathway, coupled with neuronal memories of past perceptions that emerge into consciousness. When the release theory is applied to visual hallucinations that result from vision loss/impairment, it has been hypothesized that bottom-up processing (which is usually driven by visual stimuli) inhibits spontaneous activity. This bottom-up processing simultaneously facilitates the release of these stored images, producing a visual hallucination (Cogan, 1973). It has also been argued that the excitation is simply a result of a lack of input to these neurons due to deafferentation (Fénelon, 2013: 59).

Disturbances in *top-down processing* have also been theorized to produce hallucinatory phenomena. Adaptive resonance theory states that hyperexcitability in top-down processes, specifically processes involving attention, contribute to the perception of hallucinations by occasionally activating images (Grossberg, 2000). The Perception and Attention Deficit (PAD) model assumes that hallucinations (specifically recurrent complex visual hallucinations) are caused by impairments in attention and perception combined with scene representations that are typical for an environment, but are not actually present (Collerton et al., 2005). According to PAD theory, biases in perception allow the experience of a hallucination because the individual assumes an object to be part of an environment, poor sensory activation, and a functioning scene representation.

Hallucinations may also result from the *misinterpretation of internal input* as coming from an external source. Internal input, such as a dream, may be experienced and misinterpreted during the waking state, causing hallucinatory phenomena (Fénelon, 2013: 59). The relationship between waking state, REM sleep, and non-REM sleep may be less distinct than once thought, which provides further evidence for the occurrence of dream-like hallucinations during consciousness (Mahowald and Schenck, 2001). Hallucinations may occur during the transition between falling asleep and waking, and have been reported in nonclinical populations (Fénelon, 2013: 59). During sleep, dreams are experienced because the brain is attending to

internal activity. In some circumstances, such as the sleep–wake transition state, sleep deprivation, or drug-induced states, the brain attends to both internal and external information, resulting in hallucinations (Mahowald et al., 1998).

Handedness and Language, Relationship between

Abstract

Most people are right handed with the left hemisphere controlling hand movement. This coincides with aspects of language being lateralized to the left hemisphere. Does this mean that handedness and language representation in the brain are in some way linked? How did handedness develop in evolutionary terms and developmentally? Is there a handedness gene, maybe even common for handedness and language? Is there a relation between the emergence of language and development of language before and after birth? There is a common belief that left-handers have language represented in the right brain. Is this myth or truth? More males are left-handed than females. Is this in any way related to the way language is lateralized in males and females? Left handedness has been associated with certain language disorders. What is the scientific evidence? Looking for an answer to these questions is not – as one might assume – as easy as it seems.

Introduction

Most people would probably agree that human beings look pretty much symmetrical. A closer look, however, reveals that symmetry can be quite deceiving. An important question to ask is *what* is symmetrical – the anatomy, the function, or both? Although our arms and legs may look anatomically symmetrical, one of our members may in fact be shorter than the other (anatomical asymmetry) and most people have a preferred arm or leg to throw or kick a ball with (functional asymmetry). A similar thing can be said about the brain. Although the two hemispheres may look pretty much the same to the inexperienced naked eye, they differ anatomically as well as functionally. Genetically determined anatomical brain asymmetry may be the reason for functional asymmetries observed such as language. When asked which hemisphere is dominant for language, most people would say the left hemisphere – but again, things are not that simple. When distinguishing between different speech sounds, the left hemisphere is dominantly involved while judging whether a sentence is grammatically correct involves both hemispheres. Many people would also say that the left hemisphere is dominant for language in right-handers while it is the right hemisphere for left-handers. However, this is a common misconception. Although reports vary somewhat on the exact number, research has consistently shown that about 90% of people are right-handed and about 10% are left-handed, and in the majority of right- *and* left-handers certain aspects of language are represented and/or processed in the left hemisphere. Although research supports the notion that there is some kind of relation between handedness, anatomical brain asymmetries, and the side of the brain to which language is lateralized (also referred to as (functional) language lateralization), it is far from clear what exactly this relation is.

Broca's View on Handedness and Language Dominance

In the nineteenth century, the French neurologist Paul Broca published his seminal paper in which he stated that the two hemispheres of the brain were (anatomically) perfectly similar with incidental variations from person to person but that they had different 'attributes' with language being represented and processed in the left hemisphere (Broca, 1865 translated in Berker et al., 1986). At the time, this contradicted the dominant view that the two hemispheres were functionally similar. To argue his case, Broca wanted to show that functional asymmetry of something as complex as language was, indeed, not such an outrageous exception and used right handedness as an example for a motor function dominated by the left hemisphere. He observed that most people were right-handed and only few left-handed. Further, functions that required special training such as writing, drawing, or playing a musical instrument required a division of labor between both hands with the most difficult part, "that which requires the greatest ability, precision, expression, or strength … is very generally assigned to the right hand. (…) if we consider only those that we carry out spontaneously, such as throwing a ball, hitting with our fists, handling a stick, or lifting a weight, we find that with the exception of a very small number of persons, designated as left-handed, everybody naturally uses their right hand to which the left hand is nothing but the auxiliary" (Broca, 1865 translated in Berker et al., 1986, p. 1067). Although Broca thought that education and imitation contributed to handedness, he assigned a strong 'organic predisposition' to handedness. In relation to the brain, he thought that "most men are naturally 'left-brained' and that, by exception, some of them, those called left-handed, are, on the contrary, right-brained" (Broca, 1865 translated in Berker et al., 1986, p. 1068). Broca then cited findings which suggested that the convolutions of the left hemisphere developed earlier than those of the right hemisphere in the embryo. It was thus natural for the newborn and young infant to show preference for the extremities with the more perfect innervation and become right-handed. This made humans prone to execute complex manual and intellectual actions such as articulate speech with the left hemisphere.

Broca's belief that left-handers are right-brained for articulate speech dominated research for years and is still more often than not a common belief of the layperson. Today we know that this is, in fact, a relatively rare incidence. Of the 10% of

 http://dx.doi.org/10.1016/B978-0-08-097086-8.54040-9

people who are left-handed, about 30–35% show right hemisphere language dominance. There are also right-handers who show right hemisphere dominance although this number is much smaller with about 5–6% of the 90% right-handers (McManus, 2009). In other words, one in three left-handers and one in 20 right-handers have language functions that involve processing in the right hemisphere (McManus et al., 2013; Knecht et al., 2000a,b).

The high incidence of left hemisphere language representation (at least at the word level) in right- and left-handers has meanwhile been shown in many studies. The stronger right-handedness is expressed in a person, the more likely it is that language is represented in the left hemisphere. Although being left-handed raises the chances that language is represented in the right hemisphere, this does not mean that left-handedness is a precondition or a necessary consequence of language lateralization to the right hemisphere.

Measuring Handedness and Language Dominance

Although people often determine handedness by the hand with which a person writes, this is – as also noted by Broca – a rather imprecise measure as societal pressure may have influenced hand writing preferences. In research, there is no consensus how handedness should be established. Frequently questionnaires are used such as the Edinburgh Handedness Inventory (Oldfield, 1971) which identifies the hand used for manipulating tools. These measures are, however, poorly related to manual proficiency (for a summary see Michel et al., 2013). Other measures used are quantitatively oriented such as the peg-board task, or, more rarely, observation of hand use. Another possibility is to use functional neuroimaging (such functional magnetic resonance imaging, fMRI) to measure the neural correlates of handedness during unilateral and bilateral finger movements. Compared to the previously mentioned measures, this is, however, a rather time-consuming and expensive enterprise.

Another issue to consider is what right- or left-handedness means. While classically handedness is referred to in directional terms such as left-handed, right-handed, or mixed, it is now acknowledged that the degree of handedness may be a better indicator of cerebral organization. Degree of handedness refers to how consistently a person prefers to use one hand over the other over a wide variety of tasks and magnitude. (Arning et al., 2013; Tabiowo and Forrester, 2013). Measuring and establishing handedness is thus less clear-cut as one might think.

Compared to handedness, language dominance is even more difficult to establish. Many studies rely on handedness measures and simply assume that there is a relationship between handedness and language dominance. At a group level, a correlation between handedness and language dominance has indeed been shown. At the individual level, however, handedness may not be a very good predictor. More reliable measures of language lateralization are obtained with functional brain imaging methods (such as fMRI, functional transcranial Doppler ultrasound (fTCD)), the Wada test, or the dichotic listening technique. Among these techniques, the fTCD technique is relatively low cost and easy to use. It has been validated against fMRI and the Wada test showing good correlations (Knecht et al., 1998; Somers et al., 2011).

Is There a Handedness Gene?

One question that has received considerable attention is whether handedness is heritable. Broca observed that handedness seems to run in families and attributed some heritable trait to handedness. Indeed, research has provided data showing a positive correlation between the handedness of a child and its biological parents while no such correlation is found with adoptive parents. Further, identical twins are more likely to share hand preference than nonidentical twins (for a summary see McManus et al., 2013; Ocklenburg et al., 2013). Although most researchers agree that genetic factors are involved in handedness, it has been extremely difficult to identify those factors. Two genetic models suggested that a single gene is responsible for handedness (Annett, 1998; McManus, 1985). For example, the 'right shift gene' model assumes that there is a gene that predisposes us to right-handedness. Strong right-handedness emerges if there are two copies of the gene and weak to moderate right-handedness if there is one. It may also happen that we do not get any copy of that gene. In this case, handedness will be a random outcome of chance factors and half of us will be left and the other half right-handed. Single-gene models have, however, been challenged.

While initially it was thought that handedness is a monogenic trait, recent views, mostly based on genome-wide association studies (that is statistical searches in the DNA of a large population), favor a polygenetic view. These studies suggest that at least 30–40 or even up to 100 genes may play a role in handedness and most of them are still unidentified (McManus et al., 2013). One line of research has linked handedness with a network of genes involved in establishing left–right asymmetry in the developing embryo such as inner organs and also the brain with the latter possibly influencing the development of handedness (Brandler et al., 2013). The gene variant that is most strongly associated with handedness is gene PCSK6. Disrupting this gene in mice (and other organisms) causes defects of left–right asymmetry such as abnormal positioning of organs in the body. For example, these mice may have the heart on their right and the liver on the left side. It has thus been suggested that the same biological mechanisms associated with the development of left–right asymmetry is involved in determining handedness (Brandler et al., 2013).

Generally, there is still controversy around the question whether or to what extent multiple genetic and environmental factors are involved in the ontogenesis of handedness. Some researchers have reported that more than 74% of the observed variance in handedness for writing is accounted for by environmental factors (Vuoksimaa et al., 2009). It seems that handedness may be derived from a mixture of genes, environmental factors, and cultural pressures.

Although no direct link between specific genes and handedness or forms of functional hemispheric asymmetries such as language has firmly been established, it is nevertheless assumed

that handedness and language dominance are in some way linked. Support comes from functional imaging studies that have reported an association between hemispheric lateralization of language in children and adults and handedness (Tzourio-Mazoyer et al., 2010; Szaflarski et al., 2012). If handedness and language lateralization are linked, then the gene or genes underlying handedness may also influence language dominance – at least this is how the argument goes. Hence, the study of handedness is viewed by some researchers as an indirect way of studying language dominance (McManus, 2009).

Historical and Geographical Variation of Handedness

As discussed previously, there are indications that handedness is under genetic control. Multiple forms of a single gene (genetic polymorphism) have been shown in biological systems, and biological systems vary in history and in different geographical locations (for a summary see McManus, 2009; McManus et al., 2013). Handedness also has polymorph properties, and hence the question has been raised whether handedness also varies in history and in different geographical locations. Further, as there is a correlation between handedness and language dominance, it may be that language dominance varies geographically and historically although this is difficult to prove. For handedness, however, there is indeed some support for historical and geographical variation. It seems that our primitive great ape ancestors were more or less bimanual. At some point in history (1 million years before present), so the story goes, all humans became right-handed (McManus, 2009). Subsequently, at some stage, there was some occurrence of left-handedness, about 9–10%. These numbers remained constant until between 1800 and 1950 when a dip occurred and left-handedness dropped to about 3% before the numbers rose again to 10–11% after 1950.

Concerning geographical variation, while right-handedness is more frequent in all human societies, *rates* of left-handedness vary between different continents, countries, and even within countries. For example, studies using large sample sizes found that the rate of left-handedness was 9.8% in Canada compared to 5.2% in India and 4.7% in Japan (reported in McManus, 2009). These historical and geographical differences have been explained in terms of gene frequency rather than social pressure. Assuming that handedness and cerebral lateralization are related, and using a specific mathematical model, it has been suggested that predictions can be made concerning language lateralization and disease prevalence such as dyslexia, stuttering, autism, or schizophrenia. This, however, is still open to verification.

Evolutionary Views on Handedness and Language

Observations that handedness and language evolved along the human lineage, and that the use of the right hand and language representation are dominated by the left hemisphere have led numerous researchers to postulate an evolutionary link between language and handedness (for a summary see Tabiowo and Forrester, 2013). One evolutionary theory suggests that the two hemispheres shared labor for critical survival processes. In this view, the right hemisphere evolved as dominant for controlling arousal levels (e.g., important for fight or flight actions) and the left hemisphere for processing routine behaviors such as structured sequences of actions (e.g., feeding behavior). Parallels have been seen between such structured motor activity and hierarchical structured language processes such as syntax. Some researchers have tried to establish a link between tool manufacture or tool use and linguistic processes. Right-handed tool use may be the link between left hemisphere dominant action sequences and language processes. Researchers have thus turned to animal models, and specifically great apes, to investigate the evolutionary link. Although great apes do not possess human-like language, they show neuroanatomical brain regions that overlap and show similar cytoarchitecture with Broca's and Wernicke's region in humans (Striedter, 2005, p. 327). Further, studies of *bimanual* object manipulation have reported right-handed population biases in chimpanzees, bonobos, gorillas, and orangutans (Tabiowo and Forrester, 2013). It has thus been speculated that language emerged from regions in the left hemisphere that originally evolved to cope with the hierarchical sequences of actions inherent in tool use (Pulvermüller and Fadiga, 2010). Critics counter the 'tool-use hypothesis' with the argument that tool use is not directly related to hemispheric dominance for language. As mentioned previously, the majority of left-handers do not show right hemisphere dominance for language.

Others have argued that gestural communication has played a major role in the evolution of hand preferences and cerebral asymmetries. One influential theory proposes that the region in charge of manual gestures was modified in humans such that human language emerged from gestural communication and vocalizations were gradually incorporated into the gestural system (Corballis, 2003, 2012) (see **Figure 1**). In this view, language evolved from the mirror system in primates. In humans, the mirror system was adapted for communication as a result of bipedalism. Hands were now freed and could be used to produce elaborate gestures. Over time, possibly due to environmental pressures, forelimbs became increasingly involved in other activities such as tool manufacture, use of weapons, or carrying. This scenario may have prompted a shift from manual to facial gestures in communication. Vocal sound may have been added to distinguish between otherwise identical gestures. Eventually, vocal speech replaced gestures of the face and hands and became the dominant language medium. It is assumed that the appearance of Broca's area (in the left prefrontal cerebral cortex) played an important role in the process of adding sounds to gestures.

Not all researchers agree with these views and challenge the interpretation that vocalization preceded right-handedness, the role assigned to Broca's area or the mirror system hypothesis in lateralization (for example, Annett, 2003; Beaton, 2003; Bradshaw, 2003; Dale et al., 2003; Johnson-Frey, 2003). Regardless of whether the evolutionary precursors of human language involve mainly gestures or a combination of gestures and vocalizations, primate studies as well as developmental and neuroimaging data point to the importance of gestures in social interaction.

Development of Handedness and Language Lateralization

How and when does handedness develop? There is no definitive answer to this question. There are some suggestions that handedness is already determined prenatally. One suggestion is that limb use *in utero* such as frequency of left- or right-arm movement or right thumb sucking will determine handedness. This, however, was not confirmed by systematic studies looking at the relationship between fetal lateralization and handedness (de Vries et al., 2001). Another suggestion views fetal posture and position influencing asymmetrical biases. For example, *in utero* head orientation preference leads to asymmetrical motor actions including hand and arm movements and there is some indication that this is predictive of later handedness for reaching (summary in Michel et al., 2013). There is more agreement on postnatal handedness development. After birth manual abilities change and handedness in infancy and childhood is considered unreliable and unstable before 6–10 years of age (for a summary see Michel et al., 2013).

A question that emerges is whether the development of handedness and language lateralization are linked. There is some indication that around the time when handedness becomes more stable in childhood, lexical–semantic language processing is increasingly lateralized to the left hemisphere in distinct regions of the brain (Ressel et al., 2008; Szaflarski et al., 2006a,b). Although handedness

correlates with (lexical–semantic) language lateralization for left-handed and right-handed children and adults, handedness has not been found to be a dependable predictor of hemispheric language dominance, especially in left-handers (Szaflarski et al., 2012) (see **Figure 2**). The increasing left lateralization of language with age in left- and right-handed children in specific brain regions may indicate similar developmental processes that are, so it seems, independent of handedness. However, the last words on these relationships may not have been spoken as the interpretation of some of the studies is hampered by methodological limits (such as the way handedness was established, the way performance of the task was measured in the scanner, the cultural diversity of the subjects investigated, or the fact that most data are based on cross-sectional instead of longitudinal studies).

Handedness, Language Lateralization, and Sex

Most studies report that left-handedness and ambiguous handedness is more common in males than in females, and this has been shown for children, adults, twins, and triplets (for a summary see meta-analysis by Papadatou-Pastou et al., 2008; Vuoksimaa et al., 2009; Vuoksimaa and Kaprio, 2010). Meta-analyses suggest that there is a 25% higher prevalence of non-right-handedness in males (Sommer et al., 2008). Researchers have thus pursued the question of whether gender differences observed with handedness has an effect on language lateralization.

Trying to establish a link between gender distribution of handedness and language lateralization is complicated by several issues. One is that cultural differences seem to offset the balance of the distribution of handedness of males and

Figure 2 Szaflarski et al. (2012) investigated the development of language lateralization in left- and right-handed children. Brain scans (using the fMRI technique) were obtained from 54 right-handed and 27 left-handed children while they performed a verb generation task. The task reflects lexico-semantic processing. The authors did not find an interaction between handedness and age. The top panel shows the distribution of the lateralization index (LI) (a measure of functional hemispheric lateralization) in frontal brain regions and temporal–parietal brain regions for right- and left-handed children. As can be seen in response to the word generation task, the frontal as well as the temporal–parietal regions in the left hemisphere ($LI > 0.01$) were predominantly activated in children. The bottom panel shows the lateralization growth curves for the frontal and temporal–parietal regions (frontal and temporal–parietal) for the left-handed and the right-handed group at different ages. While age did not have a clear effect on frontal lateralization (left bottom panel), temporal–parietal lateralization increased with age in both left-handers and right-handers. Figure taken from Szaflarski et al. (2012), p. 89. Legend for figure by B. Stemmer.

females (Sommer et al., 2008) (Figure 3). Another is that it is currently not clear whether language lateralization (regardless of handedness) is influenced by gender in the first place. A large meta-analysis investigated studies according to the method with which sex differences were measured. It was concluded that there was no effect of sex on language lateralization, regardless of whether dichotic listening techniques or neuroimaging techniques were used (for a review see Sommer et al., 2008) (Figures 4 and 5). Numerous individual studies and literature reviews, however, report other findings. While the relationship between sex and language lateralization remains controversial, current data suggest that handedness and sex are in some way linked.

Other studies have tried to establish a link between brain regions that have been associated with language such as the

planum temporale or Broca's area and sex and handedness. The planum temporale is a region adjacent to the primary auditory area in the temporal lobe. Decreased planum temporale asymmetry has been associated with non-right-handedness (Steinmetz, 1996; Hervé et al., 2006). Some studies have reported more asymmetry of the planum temporale in men, while others reported more asymmetry in women. A study with a large number of subjects and a meta-analysis could not find any relation between handedness and the planum temporale, or an interaction with sex (Good et al., 2001; Sommer et al., 2008) (**Figure 6**).

Classically, Broca's area has been subdivided into two subregions, the pars triangularis and the pars opercularis (areas 44 and 45 in **Figure 7**). Studies have related the volume of the pars opercularis to handedness, while no such asymmetry has been described for the pars triangularis (Foundas et al., 1995; Foundas et al., 1998; Powell et al., 2012). When trying to establish a direct link between Broca's region, sex, and handedness, no interaction was, however, found.

Why do we find such discrepant results and seem unable to come up with a clear statement? Much has to do with differences in methodological approaches and statistical power. For example, measurement techniques of the planum temporale in individual studies differ greatly. With regard to Broca's region, research has shown that the anatomical correlates of language processing go well beyond Broca's classical region (see **Figure 7**). Further, there is also high anatomical and functional variability in individual brains. In addition, considering that the number of left-handers is relatively small, a large number of subjects is necessary to find any effects, and this number is usually too high for costly neuroimaging studies.

Embodied Cognition, Handedness, and Language

Some researchers consider asymmetries of communicative gestures, manual skills, as well as concepts expressed through language as activities involving bodily actions. For example, to comprehend a concept like *jump* it must be represented in some way in our brain. Traditionally concepts like *jump* have been viewed as symbolic representations independent of modality. In theories of embodied cognition, the representation of concepts is viewed as dependent on related bodily actions such as perceptual or motor processes. For example, the representation of the concept *jump* depends on motor processes related to the action of motion. Cognition – and language as part of cognition – is considered 'grounded' in – and thus inseparable from – bodily action (for a summary see Willems and Hagoort, 2007). This implies, for example, that an action verb such as *jump* should, at least partially, be represented in the cortical motor system. Ultimately, there should be an overlap of brain processes supporting language and action, and, in order to comprehend the concept *jump*, the motor system should be activated. Indeed, neuroimaging and brain stimulation studies have shown activation of brain regions that support perception and action in response to action-related language including gestures that accompany speech (for reviews see Michel et al., 2013; Willems and Hagoort, 2007). It is assumed that an implicit mental simulation of the referent (in our example, the word *jump*) is created in these brain regions. Several neuroimaging studies have reported left-lateralized activations of cortical motor areas in response to manual-action verbs. This is not surprising considering that the left hemisphere is dominant for certain aspects of

Figure 5 Studies investigating sex differences in asymmetry of language activation. Negative values indicate larger asymmetry in females and positive values indicate larger asymmetry in males. Taken from Sommer, I.E., Aleman, A., Somers, M., Boks, M.P., Kahn, R.S., 2008. Sex differences in handedness, asymmetry of the planum temporale and functional language lateralization. language. Some researchers wondered whether these results were influenced by research that only used right-handed subjects and thus investigated the influence of handedness on the reading of manual-action verbs such as *grasp* and *throw* (Willems et al., 2010). Right-handers showed stronger activations in premotor areas in the left hemisphere and left-handers in the right hemisphere in response to reading manual-action verbs compared to reading non-manual-action verbs (such as *kneel* or *giggle*). It thus seems that actions we perform with our preferred hand have different hemispheric representations in right- and left-handed individuals.

Concern has been raised on the interpretation of some of these studies as it cannot be excluded that imagery of the action word played a role in activating the motor region. Caution has also been raised to not interpret the link between action and language as meaning that activation of the motor cortex is *necessary* for word comprehension.

Handedness, Language Lateralization, and Language Pathology

Observations that left-handedness is over-represented in some psychiatric and developmental language disorders and an observed tendency toward decreased brain asymmetries in language-related regions has raised the question of whether there is a relationship between pathological language disorders, language lateralization, and handedness.

Support for an over-representation of left-handedness in psychiatric disorders comes from a meta-analysis of over 40 studies. Left-handedness was more prevalent in psychiatric illness (Dragovic and Hammond, 2005). Abnormal lateralization of regions associated with language function have been described in the schizophrenia literature such as decreased density of gray and white matter in left temporal regions (including Wernicke's area), reduced leftward asymmetry in the planum temporale, or rightward

Figure 7 New topography of Broca's region. (a) The map of Broca's region based on the distribution of receptors of neurotransmitters and modulators shows a complex segregation of the inferior frontal gyrus and adjacent cortices (Amunts et al., 2010). In particular, it shows the presence of a series of new areas in the inferior frontal sulcus (ifs) labeled as areas ifs1, ifs2, ifj1, and ifj2, as well in the frontal operculum ('op'-areas). The areas of this region can be clustered based on their receptor architectonic pattern as shown in (b). Transmitter receptors are key molecules for neurotransmission, and therefore, indicative of function. Areas 44 and 45 of the classical Broca region are most similar to each other and they cluster with areas op8 and op9 of the frontal operculum. Interestingly, area 47 is the most different of all analyzed areas, suggesting distinct function (Amunts et al., 2010). (c) Cytoarchitectonic probabilistic map of right area 45 (Amunts et al., 1999) in the standard reference space of the single subject template from the MNI (Collins et al., 1994). The color indicates the overlap of individually mapped area 45 in common reference space. asymmetry in the pars triangularis (a subregion of Broca's area) (for a review see Li et al., 2009). In a sample of more than 100 patients with depression or a psychotic disorder (schizoaffective disorder), the prevalence of left-handedness was 40% for those with psychotic disorders compared to 11% for mood disorder (Webb et al., 2013). Although these observations are suggestive of a relation between the structural asymmetries and left-handedness, caution is necessary before drawing firm conclusions as (1) a *direct* link between these asymmetries and handedness in schizophrenia has not been established, and (2) there are also schizophrenia patients who are right-handed.

Psychosis (such as schizophrenia) is frequently accompanied by language-associated phenomena such as auditory verbal hallucinations. These hallucinations, however, are not specific to schizophrenia and also occur in about 10–15% of the general nonpsychotic population. Although the majority of these individuals does not have a clinically relevant psychotic disorder, there are indicators that suggest that they may be vulnerable for schizophrenia (Sommer et al., 2010). One difference between these two populations with auditory verbal hallucinations is that in nonpsychotic individuals language is normally lateralized while this does not seem to be the case in psychotic individuals who show decreased language lateralization (Diederen et al., 2010). It is currently not known whether auditory hallucinations are especially prevalent in psychotic patients who are left-handed and whether there is an interaction between functional language asymmetry, psychosis, and handedness.

In addition to psychiatric disorders, developmental disorders have also been associated with abnormal language lateralization and some studies report that left-handedness is more frequent in this population. Specific language impairment (SLI) is a disorder in children that is characterized by problems learning the native language without any apparent reason. SLI is frequently accompanied by problems learning to read (developmental dyslexia). Behavioral observations have suggested that the typical pattern of left language lateralization is disrupted in children with SLI and developmental dyslexia and neuroimaging studies have supported these observations (for a summary see Bishop, 2013). Despite the common belief, however, that left-handedness is associated with dyslexia, no association between handedness and language and literacy impairment was found in a review of the literature (Bishop, 2013). This has been supported by genome-wide association studies. A genetic marker located on gene PCSK6 has linked cerebral asymmetry and dyslexia. In addition, a *trend* toward greater relative right-hand skill compared to the nondyslexic population was observed (Scerri et al., 2011). However, further investigations could not establish a consistent association between hand preference or hand skill in individuals with developmental dyslexia (Brandler et al., 2013).

Autistic spectrum disorders also belong to the group of developmental disorders. Most but not all children with autistic spectrum disorders have receptive and expressive language impairments. Although the data are inconsistent, there is growing evidence that the left hemisphere structural asymmetry is atypically reduced or organized (Lindell and Hudry, 2013). Anatomical regions that have been described as asymmetrically organized include left inferior frontal brain regions (including Broca's area), posterior superior temporal regions (including Wernicke's area), the left planum temporale, and white matter tracts connecting language-relevant regions. Although heterogeneous findings with regard to decreased functional lateralization are reported by neuroimaging studies, most of the studies suggest a pattern of atypical lateralization (Lindell and Hudry, 2013). Most studies also report a higher incidence of left and mixed handedness in individuals with autistic spectrum disorder compared to the general population. The data thus appear to suggest an association between atypical handedness, atypical lateralization, and autistic spectrum disorder. As already pointed out previously, however, caution is required to draw premature conclusions as long as no direct relationship has been established between handedness, lateralization, and disease.

Happiness and Work

Abstract

The relationship between happiness and work is subject to an evergrowing empirical literature in economics. The analyses are mostly based on large-scale survey data to measure subjective well-being. Whereas one large strand of research investigates the effect of job loss and becoming unemployed, another field of study focuses on the determinants of job satisfaction evolving around employment conditions, self-employment, and potential public sector satisfaction premiums. A smaller part of the literature investigates potential driving effects of happiness on labor market outcomes. This article will give an overview about the most significant subareas of research and the empirical literature in economics to date.

Introduction

The economic research community has experienced a steep rise in the interest of analyzing individual happiness over the past two decades. Also frequently termed (life) satisfaction or subjective well-being, this field of research aims to detect information about subjective utility. Thereby, it constitutes a complementary approach to the common way in economics of measuring utility through revealed preferences or in other words, observable choices made by the individual (Frey and Stutzer, 2002). (I use the terms happiness, subjective well-being and life satisfaction interchangeably in this article, as with most economists, see, e.g., Frey and Stutzer (2002). However, as they are separable constructs, I will use the exact term when citing empirical research.) The pioneering work of Easterlin (1974) challenged the standard focus on income as the sole measure for human utility by detecting the fact that while people in the same country with higher incomes are happier than those with less income, increasing national income per person over time is not accompanied with a growing average level of happiness, at least in countries where basic needs are met. Next to this growing attention of academic researchers, policy makers are also eager to find out whether gross domestic product (GDP) alone still represents a reasonable measure of societal progress. The Stiglitz–Sen–Fitoussi Commission on the Measurement of Economic Performance and Social Progress initiated by the former French president Nicolas Sarkozy in 2008 is a prominent example of this recent development (Stiglitz et al., 2009). The Commission explicitly recommended to take into account both objective and subjective dimensions of well-being given that there appears to be an increasing gap between what people actually find important for their well-being and the information contained in the GDP level.

Parallel to this relationship between happiness and income, the question of whether and how work is related to individual happiness takes up another large fraction of the literature on happiness economics. This may not be surprising as work constitutes a significant part of people's (everyday) life. However, new classical economic theory constitutes work as a necessary evil and unemployment is seen as voluntary. According to this theory, individuals choose to be unemployed because they prefer receiving unemployment benefits and enjoy leisure time as compared to a dissatisfying wage and the time spent working. They choose to work if the offered wage exceeds a certain threshold, which enables an increase in consumption with the higher income received. In contrast, social psychologists claim employment possesses non-pecuniary values as well. As early as the 1930s, the classic study 'Marienthal,' which observed an unemployed community in Austria, revealed unemployment to have detrimental effects for individuals leading to passive resignation (Jahoda et al., 2009) by cutting their social relationships, removing their structured daily routine and lacking the feeling of contributing to society. Likewise, Layard (2011) identifies work to be the third most important factor (out of seven) affecting happiness and claims that while work generates utility gains through increased income and the related consumption possibilities, most people also attach nonpecuniary meanings to work.

When trying to understand the relationship between happiness and work, two key questions evolve: first, is having a job important at all and second, what factors contribute to job satisfaction in the case that individuals do work? While the first question may have been already touched upon in the former paragraph, there are several subquestions related to it, which refer to what actually happens when people lose their job and how this may differ according to certain conditions. While the subsequent section will address these exact questions, Section With Work: What's Important? will cover the literature related to job conditions and job satisfaction. Section Satisfaction as a Driver of Labor Market Outcomes turns to the small literature on how happiness is affecting certain labor market outcomes, thereby acknowledging the fact that happiness not only constitutes an outcome of behavior. This article concludes with Section Conclusions. (I acknowledge that there are far more studies related to the topics covered in this article, and probably also other more detailed questions are investigated, but space is limited and I intend on giving an overview of the most prominent notions and literature strands in economics.)

Without Work: Is that Bad and Why?

To detect whether being without work is an issue for individuals, a large empirical literature in economics has investigated

the relationship between unemployment and subjective well-being. (Darity and Goldsmith (1996) provide an overview on studies reporting harmful effects of unemployment from the (social) psychological literature.) These studies are usually based on large-scale survey data from different countries that measure how satisfied the individual is with his or her life, how happy the individual is currently or provides an index of mental distress by using the General Health Questionnaire (GHQ) which consists of 12 questions related to mental health. These sorts of measures pose some challenges for an accurate analysis. Unobserved individual specific factors may have an influence on answering behavior, thus omitted variable bias may arise. If these unobserved factors are time invariant however, the use of longitudinal or panel data may help to overcome these problems. The focus would then lie on *intra*-person and not *inter*person comparisons. Moreover, there is evidence of measures such as interview ratings, peer reports, and the average daily ratio of pleasant to unpleasant moods that show a strong convergence to self-reports (e.g., Diener and Lucas, 2000). Other objective validity has been shown through, e.g., brain-science data (Urry et al., 2004).

Individual and General Unemployment

The wide consensus that emerged from the literature on the effect of unemployment on subjective well-being is the detection of a detrimental effect across several data sets and countries. One of the early economic studies includes for example Clark and Oswald (1994). They use one cross-section of the British Household Panel Study (BHPS) to estimate ordered probit regressions using the GHQ mental health scale. Their findings indicate a strong negative, statistically significant correlation between unemployment and mental health, which appears larger than between any other characteristic and mental health. Whereas these results are prone to be biased with respect to the true direction of causality, they set the stage for a number of studies dedicated to a similar question. Numerous studies have used the German Socio-Economic Panel (GSOEP) for the analysis of the question of the effect of unemployment on happiness. Two early ones include Gerlach and Stephan (1996) and Winkelmann and Winkelmann (1998) that both use several waves to detect a causal effect of unemployment on life satisfaction. By using fixed effects regressions, it is possible to look at the *change* in life satisfaction scores if an individual enters unemployment as opposed to simply comparing employed and unemployed individuals given that there could also be selection of rather unhappy individuals into unemployment. Both studies confirm the negative impact of an unemployment incidence on life satisfaction, even after controlling for income. The non-pecuniary costs of unemployment appear to be large (Winkelmann and Winkelmann, 1998). These results provide some evidence against the hypothesis that it is a selection of the unhappy individuals into unemployment. Kassenboehmer and Haisken-DeNew (2009) provide more recent evidence based on GSOEP data and focus on exogenous entries into unemployment to detect a clearer causal effect of involuntary unemployment. They approximate the latter by using company closings as an exogenous unemployment shock and investigate whether these company closings, voluntary unemployment such as quitting and wanting to look for another job, as well as being fired exhibit differential effects on life satisfaction. The findings indicate strong negative effects, specifically for women, of company closures, well above the overall effect of unemployment in general, in the year of entry into unemployment. The authors interpret these results as prima facie evidence of reduced outside work options, large investments in firm-specific human capital or a family constraint. For men, the reason for unemployment does not translate into a differential impact on life satisfaction.

A study that extends the literature to more detailed evidence on the effect of unemployment on happiness includes Knabe et al. (2010). They use the Day Reconstruction Method to combine time use data and measures of emotional affect. Thereby, one is able to detect experienced utility, or in other words to get an approximation of the emotions and feelings individuals experience while performing an activity. Around 1000 employed and unemployed individuals were interviewed and asked to keep a diary on how they use their time during a specific day, their emotions during all these activities, their general life satisfaction and life circumstances. Unemployed and employed individuals can then be compared with respect to all these different domains. The study confirms previous results concerning the lower life satisfaction levels of unemployed individuals. Moreover, there is evidence that the unemployed feel less happy while performing similar activities to the employed. However, given that the unemployed have more time to perform more enjoyable activities compared to being at work, which is associated with rather negative feelings, they are able to compensate this gap in experienced utility by the amount of time the employed do not have. Therefore, average experienced utility does not differ between the unemployed and the employed.

While most studies focus on the incidence on individual unemployment, Di Tella et al. (2001) investigate how individuals' life satisfaction levels vary with their country's inflation and general unemployment rate. For the analysis, they use several waves of cross-sections from the Eurobarometer for 12 different European countries. A two-step procedure is conducted by first estimating microeconometric life satisfaction regressions for each country and calculating the mean residual life satisfaction for each nation in each year. The latter then serves as the dependent variable in a second step to represent a life satisfaction measure that is not explained by personal characteristics. This measure is then regressed on 3-year moving averages of inflation and unemployment rates for each country. Both factors exhibit negative statistically significant effects on life satisfaction. Moreover, unemployment has an even stronger effect, whereas individuals would trade off a 1-percentage-point increase in the unemployment rate for a 1.7-percentage-point increase in the inflation rate.

No Adaptation to Unemployment

Maybe becoming unemployed represents a brief shock for the individual, but over time people get used to it. For example, Clark et al. (2008) show that individuals adapt to many major life events, observed in terms of life satisfaction scores. These include events such as marriage, divorce, widowhood, and the birth of a child. Even though these events partly exert strong

effects on life satisfaction – widowhood in particular – individuals do adapt to all of them. Interestingly, unemployment represents an exception. Even after 5 years of being unemployed, life satisfaction scores have not recovered (however, a little for females). The results of several fixed-effects regressions investigating anticipation and adaptation effects with GSOEP data confirm the detrimental effect of unemployment. Importantly, this effect is not a short-term shock, but a long-lasting issue.

Scarring Effects of Unemployment

If individuals do not adapt to being unemployed, do those people who are employed, but have experienced unemployment in the past, have different well-being levels from those who have never experienced unemployment? Using GSOEP data, Clark et al. (2001) investigate this hypothesis. Fixed effects conditional logit regressions show that indeed, employed individuals with past unemployment experience report lower life satisfaction scores than those without unemployment experience. This finding is interpreted as the 'scarring' effect of unemployment. It appears to be an experience that individuals do not forget. Knabe and Rätzel (2011) examine the reasons for this finding. Again, the rich data set of the GSOEP is used, and fixed effects ordered logit estimations are performed. Interestingly, they show that past unemployment mostly exhibits an effect on current well-being before controlling for future employment prospects and individual fixed effects, including time invariant personality traits. The findings suggest only weak evidence of an effect of past unemployment on the life satisfaction levels of the employed and the unemployed when future employment prospects are taken into account. However, the fear of becoming unemployed in the future appears to have a strong negative effect on life satisfaction. Whereas on the one hand, low job security exhibits a negative effect for the employed, on the other hand insecure reemployment prospects exert a decrease in life satisfaction for the unemployed. A large part of the *scarring* effect of unemployment may therefore also be described as a *scaring* effect.

Unemployment and the Social Norm

Individuals usually do not react only upon their own situation but also compare themselves to the people around. Fulfilling certain expectations is an important factor in this regard, which leads to the question of how social norms may influence the effect of unemployment on happiness. Working can be seen as an essential social norm in many societies for individuals who are of working age. One could therefore assume that individuals who become unemployed in an environment with many other unemployed individuals are not as negatively affected as those who turn into a sort of 'outsider.' A study using BHPS data tests this hypothesis (Clark, 2003). The findings from fixed effects regressions on mental well-being scores from the GHQ-12 reveal a confirmation of the hypothesis: unemployed individuals, especially men, suffer less when the regional unemployment rate is higher, when the partner is also unemployed and when the unemployment rate of other adults in the household is higher. Whereas the results make intuitive sense at first glance, in particular the findings on the household level may have gone the exact other way. If the partner already is unemployed, then the individual's unemployment exerts even higher – especially financial – pressure on the household and may actually even make those individuals suffer more. However, these results seem to confirm a rather robust channel of a social norm effect.

Unemployment and Identity

It has been shown that unemployment causes a drop in well-being that goes beyond the material loss of income. Moreover, the creation of unemployment benefit systems in modern welfare states already contributes to moderate the income loss. In this context, a small strand of the literature investigates the relationship between unemployment and a person's identity as a channel for the drop in well-being. In other words, the individual's perception of 'self' may be threatened upon entry into unemployment. Hetschko et al. (2014) provide an example of an analysis investigating changes in life satisfaction when individuals move from unemployment to retirement. This study uses GSOEP data and performs a difference-in-difference analysis by comparing both unemployed and employed individuals moving into retirement and their potential changes in life satisfaction scores. The findings suggest a clear increase in life satisfaction for those who move to retirement from unemployment, whereas this effect is not found for those who were employed before retirement. The interpretation of this finding relates to the reinstallation of the social norm of not working when being retired compared to not working when being unemployed. The authors refer to this as positive identity effects upon retirement, thus individuals change their feeling of belonging to the new category of 'retirement age.'

With Work: What's Important?

Employment Conditions

While there seems to be a clear positive effect of being employed on subjective well-being, one should furthermore understand how certain job characteristics impact job satisfaction given the individual is actually employed. It is highly probable that while employment itself is important for life satisfaction, different employment conditions may exert differential effects on the specific satisfaction with the job. Cornelißen (2009) investigates exactly this relationship between job characteristics and job satisfaction and moreover, the impact of low job satisfaction scores on job search efforts. Using GSOEP data and conducting fixed effects regressions, relations with colleagues and supervisors, task diversity and job security are identified as main determinants of job satisfaction. Moreover, fringe benefits, the net wage, independence, influence, learning opportunities, and the subjective probability of promotion are also positive, statistically significant determinants of job satisfaction. Further regressions show that job satisfaction is a strong predictor of job search. Job search efforts increase with lower job satisfaction, which makes intuitive sense. However, this influence appears weaker with higher tenure, at a higher age, and in the public sector. Finally, the

higher job search probability is shown to be an important determinant of the probability of a job change.

Promotions

Most careers do not remain static, but rather workers receive certain promotions from time to time. The a priori hypothesis about the direction of the effect of promotions on workers' well-being is unclear. On the one hand, workers may enjoy the higher wage, greater authority and control, more challenging tasks and other privileges related to the new job status and therefore experience an improvement in their well-being. On the other hand, a promotion may be accompanied by more stress through added responsibility and longer working hours. The net effect of promotions on well-being is therefore an empirical question. A relatively recent article examines this effect of job promotions on workers' health and happiness. While several studies have focused on the effect of promotions on job satisfaction, Johnston and Lee (2013) additionally investigate the effect on certain job attributes including job satisfaction as well as on (mental) health and life satisfaction. Moreover, by introducing dummy variables indicating certain time periods before and after the occurrence of a promotion, the study allows for anticipation and adaptation effects. Potential anticipation and selection effects include: changes in well-being resulting from changes in behavior to receive a promotion such as working longer hours, from workers becoming informed about a future promotion, as well as healthier workers having higher chances of being promoted. Using several waves of the Household, Income and Labour Dynamics in Australia survey, the authors estimate a number of regressions on different subjective dependent variables. While they do not find any evidence for anticipation effects, workers indicate increased security, control, a fairer perception of pay, but also more stress and longer working hours 1 or 2 years after the promotion. Moreover, job satisfaction is significantly higher after the promotion. However, 3 years after the promotion, and despite still earning a higher wage and having more control in the job, the positive feelings vanished. The study did not find any significant effects on general health or life satisfaction, but negative effects on mental health 2 years after the promotion, which are primarily driven by anxiety-type feelings. In sum, the authors inquire as to why workers strive to be promoted as their well-being is not largely influenced and because there appears to be a negative effect on mental health. A missing argument at this point could be individuals' higher aspirations and the desire for change even though the resulting effect on well-being is unknown and may not be clearly positive.

Self-employment

A so far neglected here, but important characteristic of a job is the type of employment the worker is engaged in. More specifically, are there differences in job satisfaction depending on whether the worker is self-employed or a regular employee? A large literature is dedicated to this question. One relatively robust result implies that self-employed workers report higher job and life satisfaction (see, e.g., Blanchflower and Oswald (1998) for one of the early contributions in the economics literature). The conventional interpretation of this finding is the greater autonomy that the self-employed enjoy, or in other words 'being one's own boss,' resulting in higher job satisfaction. However, as Blanchflower and Oswald (1998) note, the selection of happier, more optimistic or cheerful people into self-employment may present another interpretation, especially when considering cross-sectional data.

Up to the current date, there have been a number of contributions in the literature that focus on more specific questions regarding self-employment and happiness, e.g., trying to shed light on the apparent satisfaction gap between the self-employed and the regular employed. For example, Millán et al. (2013) differentiate between the impact of self-employment on job satisfaction in terms of type of work and job satisfaction in terms of job security compared to paid employees. They use several waves from the ECHP to estimate generalized ordered logit models. Their results suggest that while the self-employed are more satisfied with the type of work they do, paid employees are more satisfied in terms of job security. These results appear intuitive. However, it seems important to investigate changes in satisfaction measures depending on the status before the transition into self-employment. Individuals who move to self-employment out of unemployment may differ from those who move to self-employment out of regular employment. While the former may see self-employment as a necessity, the latter may rather view it as an opportunity. Binder and Coad (2013) investigate these questions with data from the BHPS using a matching approach to better identify treatment and control groups. Their main results show that those individuals who exit regular employment to become self-employed experience a significant increase in their life satisfaction compared to those staying in regular employment, with the effect even increasing between year 1 and 2 of self-employment. When comparing those moving from unemployment to self-employment with those moving from unemployment to regular employment, no difference in life satisfaction scores were found.

Hanglberger and Merz (2011) find contrasting results to the ones presented so far. They offer a further explanation of the difference between self-employed and regular employed by focusing on anticipation and adaptation effects. They use data from the GSOEP to estimate several fixed-effects regressions. The results show large negative anticipation effects preceding the change from regular employment to self-employment and a large improvement in the level of job satisfaction upon becoming self-employed. However, this increase diminishes after 3 years, in other words individuals adapt to being self-employed. Furthermore, the negative anticipation effects were found for any job change, in particular changing jobs within regular employment as well. The authors conclude that in the long run, the self-employed are not more satisfied than regular employees. These results of course challenge many of the previous findings in the literature and show how important the data structure and quality as well as the type of methodology are for the analysis. It will surely be necessary to perform similar analyses with different data sets and for different countries. Moreover, as many authors note, the group of self-employed is very heterogeneous, including for example farmers and free-lancers. Heterogeneous subgroup effects are therefore important to take into account.

Public and Private Sector

Besides employment-specific conditions, promotions and the importance of the distinction between regular and self-employment, sector-specific conditions are another essential source for differences regarding job satisfaction. Particular attention in this regard has been paid to the difference between working in the public or private sector. Several studies found employees in the public sector on average to be more satisfied than those in the private sector (see, e.g., Luechinger et al., 2008 with a focus on life satisfaction). A recent article by Danzer (2013) aims to disentangle the channels of worker sorting and sector-specific job characteristics. In order to do that, she uses a natural experiment, namely the massive privatization process in post-Soviet countries, in particular in Ukraine. The instrumental variable approach is based on the exogenous probability of working in the private sector in post-Soviet Ukraine based on pretransition job characteristics. The data for the analysis stem from the Ukrainian Longitudinal Monitoring Survey, a nationally representative panel data set. The results suggest a positive public sector job satisfaction gap even after correcting for self-selection. Moreover, a certain part of this public sector premium with respect to satisfaction can be explained by differences in fringe benefits. However, a significant share of the satisfaction gap still remains unexplained, which may be related to job and time flexibility, differences in wage compression across sectors, and perceived job and income uncertainty.

Satisfaction as a Driver of Labor Market Outcomes

While the majority of studies in the area of happiness and work treat the specific well-being variables as an outcome, there is also a small strand emerging that aims to detect potential driving effects of happiness. Examples in the economics literature evolve mainly around the connection of happiness, job search, and labor market outcomes. For example, as already discussed above, Cornelißen (2009), among other things, investigates the effect of job satisfaction on job search.

Furthermore, Clark et al. (2008) use 20 years of GSOEP data to investigate the anticipation and adaptation effects of certain life events on well-being. They include individual fixed effects in the estimations, which help to pick up actual anticipation effects rather than selection. Their findings indicate that future unemployment reduces current well-being, which they interpret as a lead or anticipation effect. Clark (2003) and Mavridis (2010) both use BHPS data to investigate how the drop in mental well-being (GHQ score) affects the future unemployment probability. While Clark (2003) uses a simple probit model, Mavridis (2010) estimates a duration model. The findings suggest that those individuals with a higher drop in mental well-being upon becoming unemployed are less likely to remain unemployed 1 year later. Moreover, they are more likely to have a shorter unemployment duration. These results relate to the fact that those individuals who are hurt more severely from unemployment are the ones who exert more effort to exit unemployment. Clark (2003) moreover finds that those with a higher drop in their mental well-being score were more likely to have looked for work over the past week. In contrast, Gielen and van Ours (2014) find that the drop in life satisfaction upon unemployment entry does not stimulate job finding. They use GSOEP data and also estimate a hazard model. Three factors may induce the different findings: first, Clark (2003) and Mavridis (2010) do not allow the job finding rate to be influenced by unobserved heterogeneity; second, Mavridis (2010) pools women and men; and third, the subjective well-being measures are different. Moreover, Gielen and van Ours (2014) do not find the drop in life satisfaction to affect post-unemployment job quality. Finally, Krause (2013) examines the effect of an unemployed individuals' life satisfaction on future labor market outcomes. The study uses rich survey data from 2007 to 2009 of entrants into unemployment in Germany (the IZA Evaluation Dataset S) to calculate residual happiness. This residual displays higher (or lower) satisfaction levels than would be predicted by a number of demographic and socioeconomic characteristics. Subsequently, the effect of residual happiness on labor market outcomes is analyzed. Moreover, by accounting for the individual's labor market history and information about future job prospects, worries about reverse causality bias can be reduced. The findings indicate a statistically significant inverted U-shaped effect of residual happiness on the future reemployment probability and reentry wage, where the effect on wages even seems to have a cubic shape. Further investigation offers three mechanisms. First, happiness is mainly a predictor for exit into self-employment; second, only the male unemployed experience an effect of happiness upon reemployment; and third, the concept of 'locus of control' and the personality traits of neuroticism and extraversion are main drivers of the baseline effect on regular reemployment and are able to explain the effect on reemployment for males. The nonlinear effects on wages and self-employment are robust to the inclusion of personality traits. These results may give rise to the notion of an optimal level of happiness, which is not necessarily the highest, at least in terms of achievement outcomes.

Even though endogeneity concerns with respect to happiness make it difficult to detect causal effects of happiness as a driver, these few studies show that with the aid of panel data and the constructions of a measure of the drop in happiness upon some event as well as the possibility to control for several sources of bias can help to reduce potential worries. Moreover, it is important to show that happiness may in some cases exhibit a potential source of motivation for behavior. One study circumvents the endogeneity issue by the conduction of an experiment. Here, happiness increases are exogenously induced for one randomly chosen group but not the other (Oswald et al., 2009). The treatment consists of short comedy movies, whereas the control group either watches no movie or a neutral movie. The results show that improved happiness (or positive affect) increases productivity for a paid task.

Conclusions

An ever growing literature is engaged in questions that revolve around the relationship between work and subjective well-being. One large strand of research investigates the extensive margin by analyzing the effect of losing the job and becoming unemployed. Another important field of study focuses on the

determinants of job satisfaction revolving around employment conditions, self-employment, and potential public sector satisfaction premiums. A smaller part in the literature investigates potential driving effects of happiness with respect to labor market outcomes.

Work proves to be a very important determinant for people's well-being. The most obvious evidence for this statement is the detrimental negative effect that individuals experience upon becoming unemployed, which goes beyond a pure income loss effect. Losing one's identity, purpose in society, and contacts to others are identified as main reasons for this nonpecuniary cost of unemployment. Whereas these determinants are essential for the overall satisfaction with life, it has been shown that people experience rather negative emotional affect while working. Moreover, the unemployed are able to make up for the stronger negative emotional affect experienced during an activity compared to the employed with the time the unemployed have for enjoyable activities throughout the day. These results contribute to a more sophisticated view of the unemployed individual's subjective well-being. Importantly, the overall life satisfaction gap between the unemployed and the employed is not questioned by these latter results and remains crucial.

Regarding job satisfaction determinants, five patterns emerge from the literature: (1) relations with colleagues and supervisors, task diversity and job security are main determinants of job satisfaction; (2) job satisfaction predicts job search effort; (3) a promotion affects job satisfaction positively only in the short-term; (4) the self-employed seem to report higher job satisfaction scores which is probably related to greater autonomy; and (5) there seems to be a satisfaction premium in the public sector. Even though some studies lack a clear test of causality and a few others challenge these existing views, the majority of evidence seems to confirm these five patterns. Following these findings as well as Stiglitz et al. (2009), it altogether appears as if happiness research constitutes a valuable complementary source of utility measurement for both academia and policy.

Future research using high quality data structures and advanced methodologies may be able to shed light on certain contradictory results. Panel data emerge as important to take into account difficulties when working with subjective well-being data, such as individual unobserved heterogeneity. Although identifying a clear natural experiment that relates to subjective well-being is not an easy task, a more frequent use of natural experiments or other external shocks such as in, e.g., Danzer (2013) may constitute another potential direction for future research to overcome certain obstacles when comparing subjective well-being data between different groups.

Happiness: History of the Concept

Abstract

Notions of a good life have not changed much over time. All the concepts known today can be found in early writings. What has changed is the prominence attached to the aspects of the good life. Another long-term change is that conceptualizations became more specific and that empirical research has revealed their reality links, which made increasingly clear that there is no such thing as 'true happiness.'

Philosophy of the Good Life

As humans are conscious beings, they have always given thought about the quality of their lives. This thought became more systematic after the invention of scripture and the development of professional scholarship. Different notions of quality of life crystallized, often called by the same name of 'happiness.' A long-standing discussion emerged on the relative importance of these and on what constitutes 'true happiness.'

These views on the good life have been described at length in several books on the 'philosophy of happiness,' such as recently in the monumental review by Darrin McMahon (2006) entitled *Happiness: A History*. An overview of this literature is available in the 'Bibliography of Happiness' (Veenhoven, 2013a; subject sections Tb and Tc).

These historical accounts compare schools of thought over time, typically beginning with ancient Greek philosophers, such as Aristotle and the Stoics, and ending with the twentieth-century postmaterialists. The focus is on the ideas as such rather than on the social forces that shaped these. Information is drawn from writings that have stood the centuries, which involve some selection. These historiographies describe views on the good life in scholarly circles and do not inform us about views held in the general public.

Approach of This Article

In this article, I will follow a different approach. I start from a classification of notions of the good life and indicate which of these appeals most to particular parties in the debate. On that base, I make some informed guesses about prominence among scholars in the past. Next, I discuss the effect of recent empirical research on the conception of quality of life.

Notions of the Good Life

The word 'happiness' is used in various ways. In the widest sense, it is an umbrella term for all that is good. In this meaning, it is often used interchangeably with terms like 'well-being' or 'quality of life,' and denotes both individual and social welfare. This use of words suggests that there is no conflict between individuals and society. It further suggests that the quality of life could be measured unidimensionally.

Quality-of-life concepts can be sorted using two distinctions, which together provide a fourfold matrix. I have proposed that classification in an earlier attempt to bring order in the many measures used in contemporary quality-of-life research (Veenhoven, 2000). Here I use it for ordering historical views on the good life.

The first distinction is between chances and outcomes, that is, the difference between opportunities for a good life and the good life itself. The second difference is between outer and inner qualities of life, in other words between 'external' and 'internal' features. In the first case, the quality is in the environment; whereas in the latter, it is in the individual. Robert Lane (1994) made this distinction clear by distinguishing 'quality of society' from 'quality of persons.' The combination of these two dichotomies yields a fourfold matrix. This classification is presented in **Table 1**.

Livability of the Environment

The left-top quadrant denotes the meaning of good living conditions, shortly called 'livability.'

Ecologists see livability in the natural environment and describe it in terms of pollution, global warming, and degradation of nature. Currently, they associate livability typically with preservation of the environment. City planners see livability in the built environment and associate it with such things as sewer systems, traffic jams, and ghetto formation. Here the good life is seen as a fruit of human intervention. In the sociological view, society is central. Livability is associated with the quality of society as a whole and also with the position one has in society.

Life-Ability of the Person

The right-top quadrant denotes inner life chances. That is, how well we are equipped to cope with the problems of life. Amartya Sen (1992) calls this quality of life variant 'capability.' I prefer the simple term 'life-ability,' which contrasts elegantly with 'livability.'

Table 1 Four qualities of life

	Outer qualities	*Inner qualities*

Life results	Usefulness of life	Satisfaction with life

Source: Veenhoven, R., 2000. The four qualities of life: ordering concepts and measures of the good life. Journal of Happiness Studies 1 (1), 1–39.

The most common depiction of this quality of life is absence of functional defects. This is 'health' in the limited sense, sometimes referred to as 'negative health.' Next to absence of disease, one can consider excellence of function. This is referred to as 'positive health' and associated with energy and resilience. A further step is to evaluate capability in a developmental perspective and to include acquisition of new skills for living. This is commonly denoted by the term 'self-actualization.' From this point of view, a middle-aged man is not 'well' if he behaves like an adolescent, even if he functions without problems at this level. Since abilities do not develop alongside idleness, this quality of life is close to the 'activity' in Aristotle's concept of 'eudemonia.' Lastly, the term 'art of living' denotes special life-abilities; in most contexts, this quality is distinguished from mental health and sometimes even attributed to slightly disturbed persons. Art of living is associated with refined tastes, an ability to enjoy life, and an original style of life.

Utility of Life

The left-bottom quadrant represents the notion that a good life must be good for something more than itself. This assumes some higher values. There is no current generic for these external outcomes of life. Gerson (1976: 795) refers to these effects as 'transcendental' conceptions of quality of life. Another appellation is 'meaning of life,' which then denotes 'true' significance instead of mere subjective sense of meaning. I prefer the simpler 'utility of life,' while admitting that this label may also give rise to misunderstanding.

When evaluating the external effects of a life, one can consider its functionality for the environment. In this context, doctors stress how essential a patient's life is to his or her intimates. At a higher level, quality of life is seen in contributions to society. Historians see quality as the addition an individual can make to human culture, and rate, for example, the lives of great inventors higher than those of anonymous peasants. Moralists see quality in the preservation of the moral order, and would deem the life of a saint to be better than that of a sinner. As an individual's life can have many environmental effects, the number of such utilities is almost infinite.

Apart from its functional utility, life is also judged on its moral or aesthetic value. For instance, most of us would attribute more quality to the life of Florence Nightingale than that of a drunk, even if it appeared that her good works had a negative result in the end.

Subjective Enjoyment of Life

Finally, the bottom-right quadrant represents the inner outcomes of life. That is, the quality in the eye of the beholder. As we deal with conscious humans, this quality boils down to subjective appreciation of life. This is commonly referred to by terms such as 'subjective well-being,' 'life satisfaction,' and 'happiness' in a limited sense of the word.

Humans are capable of evaluating their life in different ways. We have in common with all higher animals that we can appraise our situation affectively. We feel good or bad about particular things and our mood level signals overall adaptation. As in animals these affective appraisals are automatic, but unlike other animals it is known that humans can reflect on this experience. We have an idea of how we have felt over the last year, while a cat does not. Humans can also judge life cognitively by comparing life as it is with notions of how it should be.

Most human evaluations are based on both sources of information, that is, intuitive affective appraisal and cognitively guided evaluation. The mix depends mainly on the object. Tangible things such as our income are typically evaluated by comparison; intangible matters such as sexual attractiveness are evaluated by how it feels. This dual evaluation system probably makes the human experiential repertoire richer than that of our fellow creatures.

In evaluating our life, we typically summarize this rich experience in overall appraisals. For instance, we appreciate several domains of life. When asked how we feel about our work or our marriage, we will mostly have an opinion. Likewise, most people form ideas about separate qualities of their life, for instance, how challenging their life is and whether there is any meaning in it. Such judgments are made in different time perspectives, in the past, present, and future. Mostly such judgments are not very salient in our consciousness. Now and then, they pop to mind spontaneously. Though not in the forefront of consciousness, all the time estimates of subjective enjoyment of life can be recalled and refreshed when needed. This makes these appraisals measurable in principle.

Such a subjective evaluation can also concern one's life as a whole. Jeremy Bentham (1789) referred to such appraisal as 'the sum of pleasures and pains' and called it 'happiness.'

Universal Topics

All the above-mentioned notions of the good life figure in classic thought, clearly because they all are of relevance in the human condition. A few examples suffice to illustrate their timeliness.

Livability

Since our life depends very much on external conditions, livability issues will always pop up in reflections on the good life. We see this, for instance, in imageries of paradise, such as described by Alois Hahn (1976) and also in Utopist blueprints of an ideal society on earth, such as by Thomas Moore (1869). These designs of a livable environment typically reflect the problems of the times in which they emerged. Contemporary notions of the good society focus very much on the degree to which they have solved problems of the past, such as poverty, inequality, and oppression.

Life-Ability

Quality of life depends evidently on what we make of the given living conditions, so capability issues have always figured in notions of the good life. In this context, different interest groups have emphasized different competences. 'Bravery' and 'fighting skill' were praised in the warrior classes, spokesmen for which have long dominated in the discourse. The spokesmen themselves, typically moral philosophers, rather emphasized 'wisdom.' Intellectual development was cherished

by bureaucrats, such as the Chinese Mandarins among which the teachings of Confucius were well received. 'Perseverance' and 'rationality' were emphasized in the business classes, such as in the sixteenth-century Protestant Ethic (Weber, 1905). Personal 'autonomy' is more central among contemporary psychologists and pedagogues, who see the good life more in terms of 'mental health' than of 'morality.'

Utility of Life

Since we are thinking animals, hardwired to pick up causal relations, we cannot evade wondering what our life is good for. Consequently, issues of meaning figure typically in discussions of the quality of life. All religions provide answers to that question, which often involve a promise of paradise, entrance to which is typically not free.

In the above-mentioned case of the Protestant Ethic, the meaning of life is seen in being a good steward in God's garden during one's lifetime. In some radical religions, meaning is found in the eradication of heretics. Meaning is also central in secular notions of the good life and is typically seen in furthering social justice and saving mother earth. Postmodern agnostic philosophers also emphasize meaning, but cannot decide what for.

Subjective Enjoyment of Life

Human thinking capacity has not replaced the evolutionary older affect system. Like other animals, we can feel good or bad and tend to approach situations where we feel good and avoid conditions that feel bad. Facial reflections of feeling happy or unhappy are recognized all over the world (Ekman and Friesen, 1975). As a result, hedonic appraisals are always on the scene.

In Christian mythology, Adam and Eva are assumed to have felt good before being expelled from paradise and to have suffered much after in the harsh conditions of real life. Pictorial representations of earthly paradises typically show smiling faces, such as in Chinese communist propaganda (e.g., Laing, 2004: Chapter 10).

Subjective enjoyment of life is also a recurrent topic in philosophy. Among the early Greeks, 'hedonists' such as Democritus thought of the good life as a life one likes. This view is also found in the eighteenth-century utilitarianism, such as professed by Bentham (1789).

Subjective enjoyment of life is also prominent in real-life experience. Most modern people think of it every day (Freedman, 1978). The salience of this notion appears also in the promptness of responses to survey questions about life satisfaction and a low percentage 'do not know' answers; typically less than 1% (Veenhoven, 2013b).

Historical Variations

Still these topics have not always been equally prominent in conceptualization of the good life.

Classic Focus on Morality

Virtue is central in much classic philosophy, probably because most philosophers made their living as moral advisors. In that context, personal capabilities such as honesty and faith are emphasized (right-top quadrant in **Table 1**) and also manifestations of utility, such as martyrdom (left-bottom quadrant). This emphasis on moral behavior seems to have been more pronounced in historical conditions where morality was at its weakest.

Some classic philosophers have also given thought about what makes for a good society, such as Plato (380 BC) in his 'Politeia' and in the writings of Confucius (Veenhoven and Guoquing, 2008). This emphasis is typical for developed states and is therefore more prominent in contemporary nation-states than it has ever been in the past. Today, all modern states monitor the quality of the living conditions they provide, using sophisticated systems of 'social indicators,' which become increasingly internationalized.

Moral philosophers were typically mixed about the worth of subjective enjoyment of life. Most accept it as a by-product of living a good life, rather than a manifestation of the good life as such. One reason for this reservation is in their professional involvement with moral disciplining. Another reason is probably in the poor quality of life in agrarian societies, which appears in historically high rates of homicide, poor health, and consequently a short lifetime. This historical deep point in quality of life is depicted in **Figure 1**. This misery is likely to have called for the glorifying of suffering and in the projection of happiness in afterlife, a demand to which the churches of these days have responded.

Modern Emphasis on Subjective Well-Being

During the Middle Ages, it was widely believed that happiness is not possible in earthly life and that the basis of morality is in the word of God. These views were contested in the eighteenth-century 'Enlightenment'; happiness came to be seen as attainable and morality was regarded as artificial. A lively discussion

Figure 1 Years lived in good health over human history. Source: Veenhoven, R., 2010. Life is getting better: societal evolution and fit with human nature. Social Indicators Research 97, 105–122.

of the relation between happiness and morality emerged (Mauzi, 1960; Buijs, 2007) and in that climate an instrumental view on morality appeared, in which ethical codes are seen as ways of securing a happy life.

Much of that enlightened thought is reflected in Bentham's (1789) 'Introduction to morals and legislation.' Bentham argues that the moral quality of action should be judged by its consequences on human happiness and in that line he claims that we should aim at the 'greatest happiness for the greatest number.' Bentham defined happiness in terms of psychological experience, as 'the sum of pleasures and pains,' that is, in the right-bottom quadrant of **Table 1**. His philosophy is known as 'utilitarianism,' because of its emphasis on the utility of behavioral consequences.

Though welcomed in enlightened circles in the eighteenth century, this view was rejected by the dominating ideologies of the nineteenth century and the first half of the twentieth century. The strongest opposition came from the churches, which saw little value in earthly happiness and professed a principalistic morality based on the 10 commandments. The liberals of that time also had reservations about the greatest happiness principle; in their power struggle with the aristocracy they rather emphasized freedom. Likewise, the socialists who entered the scene in the late nineteenth century prioritized social equality. Nationalism dominated in the first half of the twentieth century when the two World Wars took place, and nationalists were more interested in national glory than in individual happiness.

As a result, interest in happiness declined and one of the indications is a sharp drop in the use of the word in book titles after 1800 (Buijs, 2007). When I took a course in social philosophy in the 1960s, I encountered Bentham's greatest happiness principle as a historical topic. Yet, a revival took off at that time. Ever more books on 'How to be happy' appeared in the bookshops and happiness also became a topic in the political agenda.

This renewed interest in greater happiness was driven by several factors. One of these is that many pressing ills had been overcome, at least in the Western world. The second half of the twentieth century was characterized by peace, democracy, and an unprecedented rise in the standard of living. This gave way to more positive goals, such as health and happiness. Another factor was the development of a multiple-choice society in which individuals can choose how to live their life and therefore get interested in what way of life will be most satisfying. The rise of happiness in the political agenda was also facilitated by the weakening of the earlier ideological opposition mentioned above. The churches had declined, the liberals and the socialists got their deal, and nationalism had lost much of its appeal.

The effect of these long-term ideological shifts was much amplified by the emergence of empirical research on quality of life.

Empirical Research on Quality of Life

Quality of life became a subject of empirical research in the second half of the twentieth century, when modern welfare states developed and social engineering came to require systematic information about the well-being of the general population in order to identify needs and track progress in meeting them. Specialized research institutes were established in all developed nations and periodical welfare surveys were started. This 'social indicator revolution' (Bauer, 1967) has affected the thought about the good life in several ways.

Empirical research gave rise to greater conceptual differentiation than armchair theorizing had done in the past, both because measurement pressed to greater precision and findings revealed unexpected differences between aspects of the good life. For instance, the classic notion of 'wisdom' has crumbled in a set of rather loosely related traits (Bergsma and Ardelt, 2012).

The new quality-of-life research has also augmented the growing interest in subjective appreciation of life, that is, in the quality of life denoted in the right-bottom quadrant of **Table 1**. Life satisfaction appeared to be easily measurable in survey research, and in fact better measurable than most of the other qualities of life mentioned in scheme 1 (Veenhoven, 2000). As a result, subjective happiness became more tangible a topic; research showed how happy we are in this sense and also indicated how happy we can realistically be. Findings of this kind are well covered by the media, which has also augmented the rising prominence of subjective well-being. Moreover, social scientists have surpassed philosophers as quality-of-life specialists and also for that reason the above-mentioned philosophical reservations have lost appeal.

Rise of Research on Life Satisfaction

Empirical research on life satisfaction took off as a topic in 'social indicators research,' which emerged in the 1970s. The number of papers on this subject in the journal 'Social Indicators Research' grew so much that the specialized 'Journal of Happiness Studies' was split off in 2000. Subjective enjoyment of life became a side topic in medical 'quality-of-life research' that developed in the 1980s and in both 'positive psychology' and 'happiness economics,' which appeared around the year 2000. The number of scientific publications on happiness has grown steeply since the 1960s, as can be seen in **Figure 2**. In all these research, the leading question is what makes people subjectively happy with the major motivation being to advance this kind of happiness. Results of this strand of research are gathered in the World Database of Happiness (2013), which currently involves some 20 000 findings, some 5000 'distributional' findings on how much people like the life they live, and about 15 000 'correlational' findings on things that go together with subjective enjoyment of life.

Observed Links with Other Qualities of Life

Many of the correlational findings on life satisfaction concern aspects of the good life denoted in **Table 1**, in particular with the environmental conditions of the top-left quadrant and the personal capabilities in the top-right quadrant.

The data confirm many of the educated guesses philosophers have made in the past, such as that average life satisfaction is typically higher in democratic nations and that happy individuals tend to abide more to moral principles. Yet, the data also show much variation, not all citizens flourish equally

Figure 2 Scientific publications on life satisfaction since 1900. Source: Veenhoven, R., 2013a. Bibliography of Happiness. World Database of Happiness. Erasmus University Rotterdam, The Netherlands. Available at: http://wor;ddatabasepofhappiness.eur.nl/hap_bib/bib_fp.php.

well under democracy and morality is no sure ticket to happiness.

Some of the presumed links between qualities of life appear not to exist. For instance, average happiness in nations is unrelated to equality of incomes and negatively related to religiousness (Berg and Veenhoven, 2009; Veenhoven & Berg, 2010). Likewise, studies at the individual level found no relation with happiness and IQ (Choi and Veenhoven, 2012).

This means that the different varieties of the good life do not always go together. There is no such thing as 'true' happiness that covers all qualities, but rather quality configurations, in which some qualities strengthen each other, while others conflict. A challenge of future research is to chart configurations that are optimal in given historical conditions.

Conclusion

Notions of the good life are largely given by the human condition and pop up at all times in the great civilizations, though typically in the context of current intellectual discourses. Relative prominence varies across times and cultures. Subjective life satisfaction has gained prominence in contemporary Western society. This is partly due to the development of multiple-choice society, and another reason is that empirical research is more possible on the aspect of this good life.

Abstract

Harry F. Harlow, an American psychologist remembered for his studies of the development of the mother–infant attachment bond in monkeys, made numerous other seminal empirical contributions including developing a standardized procedure for testing the cognitive capabilities of nonhuman primates, demonstrating the capacity for abstract learning in rhesus monkeys, characterizing the long-term effects of different early social experiences, and reversing social deficits associated with early isolation rearing. Harlow's findings not only influenced researchers, theorists, and clinicians who focused on human development, but also provided the basis for several new areas of investigation.

Overview

Although Harry F. Harlow is most often remembered for his pioneering studies of the development of the mother–infant attachment bond in monkeys, he made numerous other seminal empirical contributions over his 44-year career at the University of Wisconsin. These include developing a standardized procedure for testing the cognitive capabilities of nonhuman primates, demonstrating the capacity for abstract learning in rhesus monkeys, characterizing the long-term effects of different early social experiences, and reversing social deficits associated with early isolation rearing. Harlow's findings from these and other studies with monkeys not only had major influences on contemporary researchers, theorists, and clinicians focusing on issues concerning human development but also provided the basis for several new areas of investigation. These areas of investigation continue to generate active research with both humans and nonhuman primates almost four decades after his retirement in 1974.

Indeed open any Introductory Psychology textbook published since 1960; start thumbing through the pages, and more likely than not you will come across a photograph of a rhesus monkey infant clinging to a cloth-covered dummy adjacent to another dummy, this one with a wire surface and a protruding milk-filled bottle. Along with the photo will be a description of Harry Harlow's classic 'surrogate mother' experiments, in which he dramatically demonstrated that tactile contact was more important than feeding in establishing a monkey infant's bond to its surrogate. Harlow's conclusions from these studies that "there is more to mother love than mere milk" (Harlow, 1958), had important and lasting consequences. They effectively demolished the prevailing theoretical consensus that an infant's primary social relationship is formed as a direct consequence of the feeding process, be it through oral gratification, as advocated by orthodox psychoanalysts, or by its reinforcement history, the contemporary behaviorist view. More importantly, Harlow's findings also provided compelling empirical support for specific biological foundations underlying Bowlby's attachment theory, which went on to become the predominant view of social and emotional development over the latter one-third of the twentieth century (Suomi et al., 2008). But Harlow's contributions to, and influences on, both psychology and a remarkably diverse range of other disciplines went far beyond his legacy as the father of the surrogate mother. His numerous ground breaking discoveries over a lifetime of research with monkeys have not only stood the test of time and scientific debate, but indeed provided the very basis for many new areas of scientific inquiry that still remain active.

Background, Career, and Accomplishments

Harry F. Harlow was born as Harry F. Israel on 31 October 1905 in Fairfield, Iowa, where he spent his childhood years. He left this small Midwestern town to go to college, initially matriculating at Reed College for a year (as an English major) before transferring to Stanford University, where he changed his major and then earned both his BA (1927) and PhD (1930) in psychology. His graduate advisors at Stanford, concerned that his family name might restrict his academic employment opportunities during a time of economic depression and latent anti-Semitism, suggested a name change. Harlow obliged, and later in life he often quipped that they had given him not only his degree but his very name as well. In the fall of 1930, he was hired as an Assistant Professor in the Department of Psychology at the University of Wisconsin in Madison, where he remained for the rest of his professional career. Following his retirement in 1974 Harlow moved to Tucson, Arizona, where he served as an Emeritus Professor of Psychology at the University of Arizona until his death on 3 December 1981.

Although Harlow's graduate training in comparative psychology had been largely limited to research with rodents, he began working with nonhuman primates shortly after his arrival at Wisconsin, carrying out his initial studies with a variety of monkeys and apes then residing in Madison's public Villas Park Zoo. He quickly discovered that the standard types of conditioning and memory tests then being used in studies with rats or pigeons were simply not adequate to tap the considerable cognitive capabilities of his nonhuman primate subjects. He and his students therefore began creating new tasks and test batteries that were substantially more challenging. Shortly after moving into his own laboratory building on the university campus, Harlow designed and built the first prototype of an apparatus that would profoundly alter the course of research in primate cognition and that continues to be used in primate laboratories around the world. This testing device was named the Wisconsin General Test Apparatus; it enabled an experimenter to present a large number of discrete learning and

 http://dx.doi.org/10.1016/B978-0-08-097086-8.61043-7

memory tasks in a rapid and highly standardized fashion to subject after subject (Harlow and Bromer, 1938). At the same time, he began directing most of his efforts away from broad cross-species comparisons to more focused studies using a single species – the rhesus monkey (*Macaca mulatta*), an unusually hardy and adaptive species that thrived in captivity.

Armed with a laboratory specifically designed to house and test primates, in which individual monkeys could be maintained in good physical health for year after year, and a testing apparatus that enabled the same monkey to be tested repeatedly under standardized conditions, Harlow began to change the field of animal learning. In the 1940s, he and his students created a battery of learning and memory tasks that provided a standardized 'intelligence test' for his monkeys. He then proceeded to study cortical localization of learning capabilities by lesioning different brain areas and recording subsequent differential patterns of deficits across the various components of the test battery. This research established his credentials as a physiological psychologist, and it opened up areas of inquiry and an experimental methodology that continue to be pursued in neuroscience research.

In 1949, Harlow made a major conceptual and methodological breakthrough with his discovery of 'learning sets' in rhesus monkeys. He found that monkeys presented with a long series of six-trial two-choice discrimination problems, soon learned to achieve near-perfect performance on the second and all subsequent trials of each problem. This demonstrated unequivocally that the monkeys had acquired a general strategy for problem solution, i.e., an abstract concept (in his words, 'learning to learn'), rather than a product of simple associative learning (Harlow, 1949). This finding rendered untenable neo-Decartes characterization of animals as 'reflex machines,' and it ultimately has led to increasingly more sophisticated studies of primate cognitive capabilities that foster direct comparisons with those of young human subjects. Largely because of this discovery, Harlow was elected to the National Academy of Sciences in 1951.

Harlow became interested in the ontogeny of rhesus monkey cognitive capabilities in the early 1950s, when he developed a program of research designed to precisely establish when specific cognitive capabilities first emerged during development and when they subsequently achieved adult levels. He demonstrated that infant monkeys could be both classically and operantly conditioned and performed associative learning tests at adult levels as early in life as such tests could be administered. In contrast, monkeys did not achieve adult levels of performance on more abstract problems such as learning set and oddity until their juvenile and adolescent years, respectively (Harlow, 1959). In the process of carrying out these studies, he also observed that young monkeys would solve problems and otherwise engage their physical environment in the absence of appetite rewards. This led him to conclude that in many circumstances curiosity was a more powerful motivator than a reduction of any primary drive (Harlow, 1953). These observations provided the conceptual foundation for the 'surrogate mother' studies cited above.

In the 1960s, Harlow shifted the major focus of his research from primate cognition to the development of social behavior, both normal and abnormal. He developed the concept of 'affectional systems,' in which he characterized emerging relationships formed by monkey infants with their mothers, peers, and others in the social group as differing in qualitative fashion and serving complementary roles in the socialization process (Harlow and Harlow, 1965). He and his students also studied the consequences of blocking the formation of different affectional systems via various degrees and duration of social deprivation initiated at birth (Harlow and Harlow, 1962, 1969). These studies established convincingly the importance of early social experiences for the development of species-normative adult social activities, including reproduction and maternal behavior, and they provided the conceptual and methodological basis for current studies of early experience effects on brain as well as behavior. In recognition for this research Harlow was awarded the National Medal of Science, America's highest official scientific award, in 1967.

Harlow continued his investigations of abnormal behavior during his final years at Wisconsin, generating two more areas of research in the process. First, he and his students demonstrated that the devastating behavioral consequences of total social isolation for the first 6 months or one year of life, previously thought to be permanent, could be largely reversed by exposing the monkeys upon emergence from isolation to conspecific 'therapists' deliberately chosen to not only be socially normal but chronologically younger than the isolates themselves (Suomi and Harlow, 1972; Novak and Harlow, 1975). These findings directly refuted a strict 'critical period' interpretation of social deprivation effects, providing compelling evidence of developmental plasticity and once again opening up a new area of study that remains at the forefront of developmental neuroscience research today. At the same time, Harlow set out to create a rhesus monkey model of human affective disorders, relying on earlier observations by Rene Spitz and Bowlby that certain forms of social deprivation were associated with infant and childhood depression. He and his students used a variety of social separation procedures to precipitate analogous behavioral states in young monkeys and then employed both social and pharmacological interventions to reverse to behavioral disorders (Harlow and Suomi, 1974; Suomi and Harlow, 1977). In recognition of these efforts, Harlow received the Kittay Scientific Award in 1975, the most prestigious award in the field of psychiatry at that time.

Harlow's influence on the field of psychology extended far beyond his empirical contributions, which resulted in over 323 original scientific publications over his 40-year career (a complete bibliography of Harlow's works may be found in Suomi and LeRoy, 1982). He served as Editor for the *Journal of Comparative and Physiological Psychology* for over a quarter century. He also took an active role in many scientific societies, including the National Academy of Sciences, the Society for Experimental Psychology, and the American Psychological Association, for which he was elected President in 1958. Harlow served as the Chief Psychologist for the US Army during the Korean War, and he subsequently was appointed to numerous US government planning and review committees. He played a major role in the establishment of the US Regional Primate Research Center System in the early 1960s and was instrumental in establishing the University of Wisconsin as the site for one of the seven original centers, which he directed from 1964 to 1971.

Despite all of his research activities and administrative responsibilities, Harlow maintained an active teaching role throughout his career. Not only did he train numerous graduate students and postdoctoral fellows (a total of 35 students completed their PhD dissertations under his tutelage), but he was also legendary as an undergraduate instructor, especially for Introductory Psychology, which he taught nearly every year during his tenure at Wisconsin. In addition, Harlow worked hand-in-hand with veterinary and technical personnel to establish numerous basic advances in primate husbandry, including the development of the first self-sufficient primate colony, the first large-scale primate neonatal nursery, and various quarantine and screening procedures that are still used.

Harlow was a colorful character who enjoyed dealing with controversy. He delighted in generating empirical findings that directly challenged existing theoretical dogma. In addition to his considerable skills as a writer and editor, he was a gifted public speaker, who for years was one of the most sought-after scientific lecturers in the country. As a result, he was able to present his findings not only to psychologists around the world but also to representatives of numerous other scientific disciplines, as well as to lay audiences. Indeed, 30 years after his death Harlow's scientific contributions are still cited not only by comparative, physiological, developmental, cognitive, and clinical psychologists but also by others in fields ranging from anthropology to zoology. Clearly, he was much more than the 'father of the cloth mother.'

Harmony and Social Work Practice

Abstract

Although harmony is not a popular catchphrase in the social work literature, the philosophical tenets associated with the notion of harmony underpin the mission and vision of the social work profession. This article will identify the philosophical tenets in the notion of harmony, and the ways that the relational, personal, and ecocentric arena of harmony is manifested in social work practice.

Harmony – Its Philosophical Tenets

Originating from the Latin word 'harmonia,' harmony literally means 'concord of sounds,' suggesting the coming together of different things (Li, 2008: p. 90). In Greek philosophy, the inevitable tension and struggles between opposites are recognized as the universal and creative force of harmony (Guthrie, 1962).

> The things which were like and related needed no harmony; but the things which were unlike and unrelated and unequally arranged are necessarily fastened together by such a harmony, through which they are destined to endure in the universe. (Freeman, 1983: p. 74)

Since all things are subject to internal tension that emerges from differences, harmony is manifested as 'the opposites in concert' (Freeman, 1983: p. 25), the 'accordance of the discordant,' 'a unity of many mixed,' and 'an agreement between the disagreeing' (Freeman, 1983: p. 75).

> From things that differ comes the most beautiful harmony. (Freeman, 1983: p. 25)

Harmony is probably the most cherished ideal in Chinese culture (Li, 2006). Ancient Chinese philosophers describe harmony as "various sounds responding to one another in a mutually promoting, mutually complementing, and mutually stabilizing way" (Li, 2006: p. 584).

> A single sound is nothing to hear, a single color does not make a pattern, a single taste does not satisfy the stomach, and a single item does not harmonize. (Shi Bo, a pre-Confucian scholar-minister, translated by Li, 2006: p. 584)

Like their counterparts in the West, ancient Chinese philosophers conceive diversity as a precondition of unity in the notion of harmony. Harmony presupposes differences and precludes the 'overpresence of sameness' (Li, 2006: p. 591). Confucius captures from this emphasis on the necessity of differences, an ethical and relational nexus in the ideal of harmony. In the *Analects of Confucius* (collection of ideas by Confucius and his contemporaries), Confucius preaches that

> The noble man is in harmony but does not follow the crowd; the inferior man follows the crowd but is not in harmony. (*Analects* 13.23, translated by Muller, 2012)

Ability to stand up for diversity in the quest for harmony is an ethical standard Confucius sets for the noble person. Hence, harmony is different from mindless concordance with the others. In relational terms, it is manifested in respect for different opinions and ability to work with different people. Li (2006) identifies a pragmatic attitude in addressing relational issues in the Confucian ideal of harmony.

> The attitude of harmony has a strategic significance. It makes us more willing to engage in negotiation, more willing to compromise, and less willing to resort to confrontation and conquest. It enables us to take into consideration the whole picture when considering an issue and to give each party its due. It is thus more conducive to peaceful solutions to the world's problems. (Li, 2006: p. 595)

In Taoist philosophy, harmony is a state of dynamic equilibrium that is achieved through a ceaseless process of balancing and rebalancing (Lee et al., 2009; Leung et al., 2009; Wang and Zou, 2011). Taoism underlines contradictory and opposing forces in the natural world, and metaphorically represents them as 'yin' and 'yang.' In ancient Chinese metaphysics, 'yin' and 'yang' refers to two cosmological forces manifested in many natural and social dualities such as "dark and light, female and male, below and above, cold and hot, earth and heaven, grassroots and elites" (Wang and Zou, 2011: p. 39). If well balanced or harmonized, these seemingly dualistic opposites can "exist within each other in a symbiotic relationship and interact with each other to form a holistic, dynamic and cyclical unity" (Wang and Zou, 2011: p. 41). By emphasizing the dialectic interplay of 'yin' and 'yang,' philosophical Taoism embraces dualistic holism and highlights mutuality and interdependence for achieving harmony within the person as well as between human beings and nature (Lee et al., 2009).

In sum, harmony in the philosophical sense captures the spirit of an ideal way of life, which can take place in three

different levels: (1) between individuals – at the relational level in the family, the community, the nation, and the world, whereby a harmonious relationship presupposes different perspectives and views among different social and ethnic groups; (2) within the individual – where various parts of one's body and various pursuits in life can be integrated into a well-functioning, organic whole; and (3) between human beings and the natural universe – in a healthy interplay where each gets its due (Li, 2006: p. 588). As such, harmony is a fundamental attitude with which people handle the various problems confronting life. As a profession destined to improve human well-being and the conditions of life, social work has a role to play in the harmonization processes of all three arenas.

The Relational Arena of Harmony in Social Work Practice

Social work has always celebrated the vision of a harmonious society in which human and community well-being can be secured amid differences and diversified interests. 'Promoting collective social harmony and social stability' is included as a core purpose of social work by the International Association of Schools of Social Work (IASSW) and International Federation of Social Workers (IFSW) in their global standards for social work practice (International Association of Schools of Social Work, 2004; International Federation of Social Workers, 2012). In the social work mission of maintaining social harmony, attention to differences with and among social work clients is always in place. Maintaining the social work value of 'starting where the client is' requires conscious vigilance of the individualized circumstance and cultural diversity of clients with whom the social workers work (Hugman, 1996). Since early days of the profession, individual differences among clients have also been recognized and respected in the important social work value of acceptance (Biestek, 1957; Reynolds, 1932). Acceptance is about accepting the person but not necessarily accepting their behaviors. Feelings of affiliation with the clients can coexist with respect for their autonomy, without imposing on them heavy-handed criticism or pressure to change (Berlin, 2005). By encouraging social workers consciously to restrain from attempting to mold clients to fit their own sensibilities, acceptance tempers the controlling and demeaning aspects of compassion (Berlin, 2005). The acceptance principle in social work, therefore, echoes the relational ideal of harmony to 'agree between the disagreeing.'

Meanwhile, social work represents social intervention to improve balance and harmony in society by mediating between the mainstream and dispossessed populations. As stated in the Global Standards of the IFSW and IASSW, the purpose of social work practice is to eliminate the social exclusion of marginalized, dispossessed, vulnerable, and at-risk groups at the points where people interact with their environments (International Association of Schools of Social Work, 2004; International Federation of Social Workers, 2012). In mediating between diversified groups for social harmony, social work is, however, caught in constant argument about its role in the balance between unity and differences (e.g., Bell, 2012; Berlin, 2005; Borden, 2010; Dominelli, 2002; Fook, 2002; Jones and Truell, 2012; Jose, 2010; Webb, 2009). Since early days of the profession, social work has been emphasizing its socialization function, which supports unity more than differences. Marston and McDonald (2012) describe social work as part of the modernist impulse to create a better world conducive to the normative definition of wellness. Central to the modernist project of social work is a positivist paradigm, which often carries a dominant narrative that accommodates itself to prevalent cultural values and prevailing institutional goals (Reisch and Jani, 2012). Feminist social work academics and practitioners are critical of the controlling function of social work as expressed in the positivist paradigm (Stanley and Wise, 1993; Dominelli and McLeod, 1989; White, 2006). This modernist impulse was, however, salient in the early days of the social work profession, when middle-class friendly visitors involved in creating helping as a career option subscribed to a moral view that clients could significantly reduce their problems by submitting to their advice and example (Berlin, 2005). In the 'tough love' offered to get clients work hard for what was defined by early social workers as the 'clients' best interests,' conformity to an existing social order was forged, and differences in ways that clients registered their experiences became a secondary concern (Berlin, 2005; Jordan, 2001).

This imperative to compromise individual differences for conformance to normative social expectations is perpetuated in contemporary social work practice. Emphasizing the socialization of individuals and their adjustment to their social environments, this strategy of achieving social harmony is best exemplified by what Dominelli (2002) refers to as 'therapeutic approaches' to social work, in which clients are assisted to better understand themselves and their relationships with others in the course of adjusting to the normative social order. These clinical and psychotherapeutic models in social work practice have greater concern for settling clients in existing social realities than handling the complexities of negotiating different and competing claims (Gibelman, 1999; Reisch and Jani, 2012). As acquiescence to prevalent social realities is accepted as the guiding principle of practice, difference is captured in pathological terms as inferior or a deficit. The 'othering' process in which people different from the mainstream majority are cast in a subordinate status treats clients as dependent beings, who are expected to subscribe to the technique of benign control and superior knowledge of the social workers in acquiring the survival strategies for coping with their predicaments (Dominelli, 1998, 2002, 2005; Johnson et al., 2004). Differences as such are objects for eradication through assimilation of the minorities into the dominant culture (Hugman, 1996).

In emphasizing the adjustment of clients to social realities, the maintenance-oriented view of social work and the movement toward clinical and psychotherapeutic models in social work practice depoliticalizes issues such as unemployment and poverty within society (Davis, 1994; Dominelli, 2002; Strier and Binyamin, 2010). The focus on unity and conformity to the structural order in this depoliticalization process reinforces the political function of social work in forging social and political stability. The recent inauguration of social work in the People's Republic of China

exemplifies the political role of social work, as the Chinese Government sets out to develop a strong social work force for 'constructing a harmonious socialist society' (Central Committee of the Communist Party, 2006). Promising to implant the techniques of responsible citizenship and supplant failing morals with morals of service and dedication under the tutelage of expertise, social work claims a sophisticated technology for governing at a distance, which makes it the right candidate to ease the social tensions that the Chinese Government can no longer manage with an authoritative and hierarchical governance system (Leung et al., 2012; Miller and Rose, 2008). The social harmony that the Chinese Government attempts to actualize is a state of stability in which unity under the 'socialist order' is emphasized. By socializing individuals to conform to preexisting structural order, sameness displaces diversity in this approach to achieve social harmony. Harmony as such is a state of unity achieved by silencing differences and sustaining control of the 'others' by existing power relations. Coined in this conformist sense, harmony can be a disguise for oppression.

In the critical tradition of social work, the 'othering' of difference is, however, received with much discomfort by critics who reject the use of binary opposites in defining social work outcomes. Proponents of antiracist and feminist social work underpin the unity–diversity dialectics in social work, acknowledging similarities and common causes among social work clients amid their considerable differences and uniqueness (Dominelli, 2008; Dominelli and McLeod, 1989; Phillipson, 1992; White, 2006). Practicing equality and social justice in critical social work practices 'requires the practitioner to value difference in lifestyles and identities' instead of settling for 'a uniform conformity in others' (Dominelli, 2002: p. 9). From a postmodern perspective, Fook (2002) calls for "a wealth of diverse meanings, experiences and identities" to be represented in social work discourse (Fook, 2002: p. 13). 'Difference' to be sought and embraced in the complexities, contradictions, and ambiguities underpinning everyday practices plays a key part in the ontology of an alternative paradigm for social work (Bell, 2012; Borden, 2010). Recognizing the damaging consequences in 'aspects of globalization that standardize and marginalize people,' Jones and Truell (2012) also embrace differences across regions as they consider a global agenda for social work, and support the diversity of interpretation of broader global standards for social work in regional contexts (Jones and Truell, 2012: p. 458). As the fluid, heterogeneous, and dynamic realities in practice are increasingly emphasized by proponents of progressive practices popularly known as emancipatory or antioppressive practice, contemporary social workers become more sensitive to differences within the population they serve (Bell, 2012; Dominelli, 2005; Strier and Binyamin, 2010).

Representing interactive spaces within which people construct their lives, community as an important platform of social work intervention is also fused with differences and diversities (Dominelli, 2007). Conventional conception of community as 'a unified constellation of people with shared goals' does not adequately capture plurality and contradictions that prevail in the community (Dominelli, 1999, 2005). At the same time, while collective interests of members in community create bonds of solidarity and symbolic identification to make it 'the warm glow of inclusion,' community can also be the 'cold icicles of exclusion' when differences from other communities separate insiders from outsiders (Dominelli, 1999: p. 442). The 'othering' processes that privilege insiders and foster the penetration of hegemonic discourses can also occur within the community or in the name of it (Dominelli, 2007).

The escalating call to embrace differences in social work practice encourages a broader view of politics, which challenges the normative boundary and the 'othering' processes that deny the human, social, and political rights of clients (Dominelli, 2002). In recognition of the inevitable power relationships between the social workers and their clients, achieving harmony among diversities requires social workers to reflect upon and examine how their 'biases, assumptions and cultural world-views' affect the ways they 'perceive difference and power dynamics' (Sakamoto and Pitner, 2005: p. 441). Critical consciousness and courage to challenge power differentials becomes a renewed professional ethic for social workers. Dominelli (2008) highlights in her practice guidelines for social work practice aiming to address diversities that social workers should 'think of the world as organized holistically with interdependent social relations' that acknowledge differences rather than submerge differences through 'binary dyads rooted in relations of superiority and inferiority'; and 'create new narratives' and 'form alliances' across social divides to 'ensure that differences are considered' and 'equality across differences' established (Dominelli, 2008: pp. 225–226). The social harmony for which an emancipatory approach to social work is advocating is a collaborative process for integrating 'different forces in a fluid yet dynamic world,' rather than a 'conformist harmony' that seeks to conform to a firm, preset and rational order imposed onto the world (Li, 2008: p. 91).

> If harmony is founded on a linear, logical, inherent structure of the world, we need to discover this reality and conform to it; if harmony is a multidimensional, inclusive, and dynamic creative process, we need to participate in a proactive way to generate it through collaboration. (Li, 2008: p. 95)

Such reflexive collaboration with clients realizes the radical notion of harmony, which Li (2008) describes as 'deep harmony.'

The Personal Arena of Harmony in Social Work Practice

Harmony is also a state of wellness within individuals – "when in harmony, people thrive, are resilient beyond expectation, and contributes in a synergistic manner to those around them with their energy" (Hodge et al., 2009: p. 216). Committed to enhancing human well-being, social work has always been playing an active role in maintaining harmony within the person. The bio-psycho-social construction of the self and human existence in conventional social work practice, however, are increasingly considered inadequate for promoting resilience and peace cherished in the ideal state of

intrapersonal harmony (Lee et al., 2009). Lee and colleagues criticize contemporary clinical social work practice as employing dualist thinking to conceptualize the person as one "who has distinctively separate and interrelated cognitive, behavioral, and affective domains, but not as a holistic and connected being" (Lee et al., 2009: p. xxvii). In the tendency to compartmentalize the person in terms of cognition, behavior, and affect, different therapeutic interventions assume the linearity of change enabled by specific therapeutic techniques suggested by respective theories – e.g., the emphasis on intrapsychic forces in psychoanalysis, thoughts in cognitive theories, and observable behaviors in behavioral theories (Chan et al., 2002; Lee et al., 2009; Leung et al., 2009). Informed by Eastern philosophies and postmodern thinking, alternative helping strategies are gaining momentum in the purview of clinical social work practices. These alternative approaches view the mind, the body, and the spirit as interconnected entities, and take a holistic and preventive view of a person's problem in the project of helping (Chan et al., 2002; Henderson, 2000; Lee et al., 2009; Leung et al., 2009; Weick, 1987).

The influence of Eastern philosophies is apparent in this holistic approach to achieve harmony within the person. Transcending the Western body–mind duality, the yin-yang perspective in Taoism sees personal wellness as a harmonious interplay between the body–mind–spirit components of a person (Chan et al., 2002; Lee et al., 2009; Leung et al., 2009). Believing that seemingly opposite forces are in fact complementary, the criterion for well-being is not the possession of any one attribute or characteristic, but the presence of a dynamic balance between diverse forces (Lee et al., 2009). In this integrative body–mind–spirit model of clinical social work practice, 'human existence is a manifestation of physical, emotional, cognitive, social, and spiritual being' interconnected into a whole, and wellness is therefore the 'harmonious dynamic equilibrium within the self' (Ng et al., 2008: p. 68). As clients going through their predicaments may experience disruption in one or more of the body–mind–spirit domains, a harmonizing intervention in social work is to reorganize and revitalize the persons for a new, fluid, and balanced state of total being (Chan et al., 2002; Lee et al., 2009; Leung et al., 2009; Ng et al., 2008). Considering spirituality, life values, and personal meaning as the foundation of the mind and body, the goal of social work intervention in this integrative body–mind–spirit approach is to encourage spiritual transformation in the clients (Lee et al., 2009). Translating these philosophical premises into practice principles, social workers are required to look at the whole and understand the dynamic balance within it, while appreciating change as a process of moving toward new balance (Leung et al., 2009).

The body–mind–spirit approach to clinical social work practice advocates for a harmonizing process to regain balance and harmony within the person (Lee et al., 2009; Ng et al., 2008). This harmonizing process involves four stages: (1) awareness of disharmony and imbalance of the system; (2) strengthening the system to restore balance; (3) harmonization of body and mind by facilitating recognition of the interconnectedness of body and mind; and (4) spiritual transformation to experience the course of life by redefining a goal-oriented pathway of life (Ng et al., 2008). Novel intervention techniques emerge from this holistic perspective in restoring wellness for the clients, including Tai Chi and Qigong exercises, body scan, breathing meditation, mindful tea drinking and eating, and cognitive reconstruction by acknowledging and accepting impermanence and unpredictability to enable clients to regain self-control by letting go of control (Lee et al., 2009; Ng et al., 2008). Although this alternative and holistic approach to clinical social work practice is largely derived from Eastern philosophies, a growing interest in a spiritual approach for balance and harmony within the person is not confined to the Chinese societies (Chan et al., 2002). In Henderson's survey of the use of alternative therapeutic methods among social work practitioners in America, mind–body techniques were provided to clients by most practitioners (Henderson, 2000). The spiritual side of clinical social work practice also receives increasing attention in the West, especially in cases of bereavement, terminal illness, and immigration where national communities are invoked (Canda and Furman, 2010; Seinfeld, 2012). A 'community of others' (Lax, 1992) comprising individuals who share similar experiences is important for supporting spiritual transformation in clients (Lee et al., 2009). Social work groups that harness collectives of support and mutual aid provide relevant medium for engendering the harmonious equilibrium within the self (Ng et al., 2008).

The Ecocentric Arena of Harmony in Social Work Practice

Harmony as balance, interrelationship, and complementarities also applies to the relationship of human beings with nature. Ancient Chinese philosophy supports the human ideal of achieving harmony not only within the human community but also with the rest of the cosmos, to allow 'myriad things to flourish' in a human–nature integration (Lee et al., 2009; Li, 2006). Addressing human's interaction with the ecological environment is, however, not a popular purview of social work practice. Although social work claims to espouse an ecological perspective and ground its practice in the person-in-environment assessment framework, 'the environment' in the social work literature refers primarily to the sociocultural or psychosocial environment, not the ecological environment (McKinnon, 2008; Norton, 2012; Zapf, 2005). The unexamined assumption of the superiority of human beings over the natural world, which allows human wants to dominate nonhuman entities, is a cause of concern to critics who lament the absence of ecological consciousness in social work practice (Besthorn, 2012; Coates, 2003; Dominelli, 2012; Gray and Coates, 2012; Norton, 2012). Conceiving ecological devastations as rooted in 'blind obsession with markets and profit, and materialistic and consumerist lifestyles' (Coates, 2003: p. 8), critics ascribe the cause of the planetary crisis to the 'competitive-individualistic-rational' belief system and 'modernism's innate attitude of superiority' (Coates, 2005: p. 33) that fails to appreciate our connection to other life forms and nature (Coates, 2003, 2005; Coates et al., 2006; Gray et al., 2008; Hart, 2002; Hodge et al., 2009; Zapf, 1999, 2005).

The role of social work in maintaining harmony between the natural universe and human beings has been attracting attention of the social work community lately. Environmental sustainability is included as a priority area for international effort in the global agenda for social work and social development promulgated jointly in 2012 by the IFSW, the IASSW, and the International Council on Social Welfare (IFSW, IAASW and ICSW, 2012). Some social work scholars appeal to expand the definition of client's life spaces and revise the configuration of the person-in-environment framework to include the natural world (McKinnon, 2008; Norton, 2012; Zapf, 2005). Critics are also calling for a new paradigm of social work practice that is premised on connectedness between human beings and nature, to facilitate a nondestructive and mutually beneficial human/nature relationship (Besthorn, 2012; Coates, 2003; Dominelli, 2012; Norton, 2012). This escalated concern for the relationship of the human community with nature is attributed to increasing awareness of the strong link between environmental problems and social problems, amid relentless industrial and technological progress and expansion of capitalism (Coates, 2003; Kemp, 2011; Norton, 2012). Directly or indirectly, the burdens of ecological devastations fall most heavily on poor, marginalized, and vulnerable populations concentrated in geographically undesirable and spatially isolated communities; and this legitimizes the ecosocial emphasis of social work in its quest for social justice (Gray and Coates, 2012; Kemp, 2011; Norton, 2012).

Dominelli (2012) describes social work with an ecocentric emphasis on holistic practices as focusing on the "interactions between socio-economic and physical environmental crises and interpersonal behaviors that undermine the well-being of human beings and Planet Earth" (Dominelli, 2012: p. 25). This highlights the political nature of what she terms 'green social work,' which addresses the sociopolitical and economic forces underlying the unequal distribution of power and natural resources. Dominelli (2012) translates this political and moral project of social work in the ecocentric arena into the following practice activities: (1) raising awareness of different disaster scenarios including poverty, and their outcomes; (2) maintaining dialogues about polices with policy makers, practitioners, and service users to encourage the sharing of resources and green technologies across the world; (3) lobbying for preventive measures locally, nationally, and internationally to create egalitarian and sustainable models of development; (4) mobilizing and developing resilient responses to disasters; (5) researching issues and problems to formulate new ways of looking at the world, and of living within it; and (6) training people to value and respect differences, and observe a duty of care toward the environment (Dominelli, 2012: pp. 201–2).

Apart from tackling ecological problems that affect human lives, proponents of ecocentric social work practice are also interested in the spiritual and philosophical insight obtained from the "deeper connection with, and more sensitive interplay, between humans and the non-human world" (Besthorn, 2012: p. 250). At the core of the philosophy of ecology is a 'person-with-environment' perspective, which calls for deep questioning of prevailing knowledge, values, and social institutions that maintain human dominance over nature, and recognizes the fundamentally spiritual nature of the ecological challenge (Besthorn, 2012; Coates, 2003). Underpinning social work's concern for harmony with Mother Nature is a moral and spiritual ethos that sets out to question the arrogance of seeing 'humankind as in control of and superior to other species' (Coates, 2003: p. 76). A spiritual change engendered by global consciousness is expected to promote deep respect for and harmony with nature. In practice terms, Coates (2003) advocates that social work can play an important role in helping people break free of a sense of superiority and separateness, and "recognize the need for a shift in consciousness away from the passion to consume, the centrality of economic growth and the drive for more" (Coates, 2003: p. 76).

Conclusion

As a philosophical premise, harmony is a state of balance, complementarities, and interdependence in the inevitable presence of differences. Manifested in the relational, personal, and ecological arena, harmony emphasizes acceptance of diversity rather than the 'othering' of differences, supports holistic integration rather than compartmentalization, and is achieved through cooperation rather than assimilation. Social work has long played a significant role in handling the unity–diversity dialectics in the relational arena. In mediating among diverse social groups with differing backgrounds and interests, intervention approaches emphasizing conformance and socialization of the minorities coexist with progressive practices that encourage critical consciousness of the social workers to embrace diversities. Essentially, social work contributes to social harmony by upholding and encouraging the value of acceptance in the face of difference. Confronting the 'othering' process by reflexive collaboration with clients also promises a state of 'deep harmony' that social work practice in a fluid yet dynamic world calls for. In the intrapersonal arena, the yin-yang perspective and its emphasis on the harmonious interplay between the body–mind–spirit components of a person encourages growing interest in an integrative and holistic approach to clinical social work practice. A 'social community of others' (Lax, 1992) comprising those who share similar experiences often plays an important role in facilitating the spiritual transformation required of harmony in the intrapersonal arena (Lee et al., 2009). While spiritual transformation is important for achieving the harmonious dynamic equilibrium within the self (Ng et al., 2008), it is also a necessary process to maintain harmony between human community and the natural world, amid modernist thinking that fuels human arrogance in rejecting peoples' embeddedness in nature, and blind obsession with materialistic and consumerist lifestyles (Coates, 2005). Maintaining harmony with the natural universe is also a political project, in which the sociopolitical and economic forces underlying the unequal distribution of power and natural resources are addressed (Dominelli, 2012). Committing to equilibrium and balance in the dynamic interplay among differences, the philosophical notion of harmony renders social work practice in various arenas a political and spiritual project.

Hart, Herbert Lionel Adolphus (1907–92)

Abstract

Herbert Lionel Adolphus Hart (1907–92) revived the tradition of analytical jurisprudence, exploring both the concept of law in general and a number of specific concepts – causation, rights, obligation, responsibility, rules – that structure legal reasoning and doctrines. His theory of law lies in the positivist tradition of Bentham and John Austin, which asserts that law is a social artifact separate from morality. Hart's innovation was to draw on linguistic philosophy to elucidate the relevant concepts by examining their operation within the practical contexts in which they are used, and to theorize law as a system of primary and secondary rules with both internal and external aspects. Hart also contributed to moral and liberal political philosophy, making influential interventions in normative and policy debates about matters such as capital punishment, abortion, and the regulation of homosexuality. His treatment of these issues was located within a tradition stretching back to Hobbes, Hume, Locke, and, most obviously, J. S. Mill, to which Hart contributed, among other things, an elaboration of principles limiting the proper scope of state action, a novel account of the justification of punishment, and an analysis of the relationship between utility and rights.

Introduction

Herbert Lionel Adolphus Hart was born on 18 July 1907 in the spa town of Harrogate, England, where his family, which was Jewish, ran a furrier's business. Hart's was the first generation of the family to receive a university education: he studied at New College, Oxford, where he took an outstanding first class degree in Greats (ancient history and philosophy) in 1929. He then qualified as a barrister, and enjoyed a successful practice at the Chancery Bar throughout the 1930s. In 1940, he became a civil servant working in military intelligence; in 1941 he married Jenifer Fischer Williams, a civil servant in the Home Office, who was later herself to become an academic.

During the war, Hart's keen interest in philosophy was stimulated by regular conversations with Stuart Hampshire and Gilbert Ryle, who were working in a related department, and who introduced him to the new movements in linguistic philosophy. In 1945, after some hesitation, but encouraged by his close friend Isaiah Berlin, Hart accepted a fellowship in philosophy at New College. Despite his 16 years outside the academy, he established himself quickly as a leading member of the influential group of analytic philosophers, including Ryle, J. L. Austin, G. A. Paul, and Friedrich Waissman, working in Oxford at the time. Such was his reputation that, despite having published only three papers, he was in 1952 elected professor of Jurisprudence at University College, Oxford. During his tenure of the Chair, he revived what had become an intellectually sterile subject, bringing to jurisprudence the rigor of a philosophical method of which it had been deprived since the days of Bentham and John Austin, and introducing the fresh insights of Wittgenstein's and, primarily, J. L. Austin's philosophy of language.

Outside the United Kingdom, his reputation was especially strong in the United States, where he spent several periods, notably at Harvard in 1956–57, and in Israel, which he first visited in 1964. He was elected President of the Aristotelian Society in 1959 and Fellow of the British Academy in 1962. In 1968 he resigned from the Chair, taking up a senior research fellowship at University College, Oxford, in order to devote himself to the editing and analysis of the works of Bentham. From 1967–73 he served as a member of the Monopolies Commission; he also chaired a committee that made important recommendations for the reform of Oxford's governance in the light of student unrest in the late 1960s. From 1973 to 1978 he was Principal of Brasenose College; following his retirement he returned to University College as an honorary fellow. He died in Oxford on 19 December 1992.

Hart's Contribution to Legal, Moral, and Political Philosophy

Hart's intellectual contribution lies in two distinct but related fields. First, he revived the tradition of analytical jurisprudence, exploring both the concept of law in general and a number of specific concepts – causation, rights, obligation, responsibility, rules – that structure legal reasoning and doctrines. In this work, Hart emphasized J. L. Austin's assertion that one may use a "sharpened awareness of words to sharpen our perception of the phenomena" (Hart 1961: v). He insisted, however, that the task was not one of simple definition: rather, the aim was to build a theory or elucidation of the relevant concepts by examining their operation within the practical contexts in which they are used, and paying heed to the 'open texture' of language, with its core meaning surrounded by an unsettled penumbra (Hart, 1961; see also Hart, 1982, 1983; and for commentary, Bayles, 1992; Cane, 2010; Coleman, 2001; Gavison, 1987; Hacker et al., 1997; Kramer et al., 2008; Lacey, 2004; MacCormick, 2008; Martin, 1987; NYU Law Review, 2008; Simpson, 2011). Perhaps the most outstanding example of these methodological commitments lies in Hart and Honoré's monumental *Causation in the Law*, first published in 1959, which sets its conceptual analysis of causation within the context of hundreds of legal cases, and which draws criteria for the identification of causes out of the common sense understandings that underlie everyday usage in the relevant contexts Hart and Honoré (1959).

Hart's second contribution was in the fields of normative legal, moral, and political philosophy (Hart, 1955, 1963, 1965, 1968). Building out from his analytic conceptions, he made highly influential interventions in normative and policy debates about matters such as capital punishment, abortion, and the regulation of homosexuality. His treatment of these issues was located within a tradition stretching back to Hobbes, Hume, Locke, and, most obviously, J. S. Mill, to which Hart contributed, among other things, an elaboration of principles limiting the proper scope of state action, a novel account of the justification of punishment, and an analysis of the relationship between utility and rights.

To understand why Hart's work in analytical jurisprudence had such an extraordinary impact, one has to understand something about the development of jurisprudence in the century preceding his election to the Oxford Chair. From the late eighteenth to the midnineteenth century, the utilitarian thinkers Jeremy Bentham and his disciple John Austin had developed an influential theory of law known as 'legal positivism.' Rejecting the idea that law derives its authority from God, or from some metaphysical conception of nature or reason – so-called 'natural law' – Bentham and Austin argued that law is essentially man-made: it is a command, backed by sanctions, issued by a political superior or sovereign, to whom the populace is in a habit of obedience. This positivist theory had, however, been little developed since Austin's death. The one exception was the brilliant Austrian jurist Hans Kelsen, whose theory of law as a system of norms was, however, mainly influential on the continent of Europe. In early twentieth century Britain, after the decline of historical jurisprudence, the slow development of legal education in universities contributed to the impoverishment of the tradition of analytical jurisprudence, which concerned itself primarily with the decontextualized analysis of legal terms such as ownership, possession, or the corporation. This analysis was not enriched by any systematic exchange with philosophy, nor was there any attempt to link it to any broader idea of the nature of law, or to consider how technical legal concepts assisted law to serve its various social functions. In the United States, by contrast, jurisprudence had moved in a sociological direction that arguably emphasized the empirical at the expense of a sustained examination of the conceptual dimensions necessary to an analysis of law's distinctive normativity. Prescriptive questions about what purposes law ought to pursue were left to the attention of moral and political philosophy – the latter itself a field that was relatively stagnant at this time.

Hart's first single-authored book, *The Concept of Law* (1961), which stands as his most important work, claimed to provide a general, descriptive theory of law that was at once a contribution to 'analytical jurisprudence' and to 'descriptive sociology.' In other words, he sought to elucidate a concept of law that would be relevant to an understanding of all forms of law, wherever or whenever they arose. In pursuing this project, Hart returned to the insights of Austin and Bentham, but – in a crucial innovation – combined their methods with those of the new linguistic philosophy represented by J. L. Austin and Ludwig Wittgenstein.

The nub of Hart's theory is the startlingly simple idea that law is a system of social rules structurally similar to the rules of games such as chess or cricket. The rules are of different kinds, with complementary functions. Some – 'primary rules' such as criminal laws – directly govern behavior; others – 'secondary rules' – provide for the identification, interpretation, and alteration of the former. Distinctive among these secondary rules is the 'rule of recognition.' This rule provides criteria by which officials identify valid rules belonging to the legal system. It, therefore, also serves to identify the content of one particular legal system. Yet it is not, Hart argued, itself a valid rule of the system. Rather, it exists in the constellation of official attitudes and practices. The existence of a legal system is hence, fundamentally, a complex matter of social fact.

Like his nineteenth-century counterparts, Hart therefore insisted that law is a social, human invention: though legal rules generate genuine obligations, they are not moral rules. Their authority derives not from their content but from their source, which lies in a distinctively institutionalized system of social recognition. For example, the rule that we should drive on the left is authoritative not because there is any intrinsic value to driving on the left. Rather, it is because the rule can be identified in accordance with an agreed set of criteria for recognition, such as parliamentary enactment or judicial precedent. Precisely the same is true, moreover, of legal rules that overlap with moral standards: the legal prohibition on murder is not the same as, and derives its validity in a different way from, the moral injunction against killing. Hart also teased out, however, what he saw as important grains of truth in the natural law tradition. While he insisted that the connection between law and morality was a contingent one, he also pointed out that a rule-based legal order brings with it a distinctive conception of formal justice. He also argued that, given certain features of human beings – our physical vulnerability and limited altruism, and the limited resources of the natural world, for example – legal systems, given their purpose of facilitating human survival, would have to include a core set of rules governing – justly or unjustly – matters such as physical integrity and property. This he termed, perhaps misleadingly, "the minimum content of natural law" (Hart 1961: 189–95).

Hart's account of how legal rules are recognized as valid served, on the other hand, to distinguish law from a mere system of force, or 'orders backed by threats.' For – crucially – according to Hart, legal rules have not only an external but also an internal aspect: we know that a rule is in existence not only because it is regularly observed, but also because those subject to it use it as a reason or standard for behavior, criticizing themselves or others for breaches of the rules. Here the linguistic philosopher's focus on the understandings embedded in ordinary usage becomes important. For example, Hart explores the distinction between habitual behavior (going to a café on Sunday morning) and rule-governed behavior (going to church on Sunday morning); between being obliged to do something (handing over money because someone threatens to kill you if you refuse) and having an obligation to do it (paying your taxes). Of crucial importance to his status as a positivist is his insistence that the decision to adopt an 'internal attitude' to legal rules can be based on a variety of reasons, ranging from moral commitment to mere pragmatism: indeed, for a legal order to exist, it is theoretically only necessary for the officials of the

system to adopt an internal attitude to its rules. In his elucidation of the internal attitude, Hart claimed to have detached the concept of law from that of sanction: the normativity of law derives from the internal aspect of rules and not from the threat of punishment for their breach.

By moving from the early positivist notion of law as a sovereign command to the notion of law as a system of rules, Hart produced a theory that resonated with the impersonal idea of authority embedded in modern democracies, providing a remarkably widely applicable rationalization of the nature of law in a secular and pluralistic world. He also offered an account of legal validity that purported to explain the (limited) sense in which citizens have an obligation to obey the law. Unlike the 'command' theory, Hart's concept of law accounts not only for laws that impose duties but also the wide variety of laws that confer powers upon or create normative facilities for citizens: the law of property, contract, marriage, or succession, for example.

Hart also succeeded in reviving the idea that the project of jurisprudence should be not only to provide a clear, descriptive concept of law; but also – though as a separate project – to elaborate a framework for systematic criticism of law and for law reform. Hart's work became increasingly concerned with these prescriptive questions: from the late 1950s on he published highly influential papers dealing with issues such as the punishment of those who had committed what would now be regarded as serious crimes in Nazi Germany: capital punishment, the decriminalization of homosexuality, and the legalization of abortion. In these works, and in his widely publicized debate with the conservative judge Patrick Devlin, he regenerated a liberalism that finds its roots in J. S. Mills' *On Liberty* (1859). In *Law, Liberty and Morality*, Hart (1963) argued, as against Devlin, that democratic states are not entitled to enforce moral standards for their own sake. With the exception of special cases where paternalistic legislation can be justified, or where grave public offense is at issue, the state should respect individual freedom, intervening only to punish the commission of tangible harms. This books stands, over 30 years after its publication, as the resounding late twentieth-century statement of the most influential genre of liberal social policy. The philosophical ideas on which it rests are articulated closely with those expressed in Hart's conception of rights as founded in respect for individual human liberty and choice (Are there any natural rights?), and in his argument that consequentialist aims of punishment should be tempered by considerations of individual fairness in the distribution and quantum of punishment (Hart, 1968).

Hart's Importance for the Social Sciences

Since the mid-1960s, Hart's work has been subject to intense scrutiny and criticism. The most significant criticism has come from two different directions. First, from the direction of natural law theory, it has been argued that, ultimately, the reason why those subject to legal rules adopt an internal attitude to them has to do with moral factors, and that consequently Hart's restricted sense of legal obligation, and with it his distinction between law and morality, collapses. Second, from the direction of the social sciences, it has been argued that although the techniques of analytic philosophy may establish that law is simply one form of social rule, the further question of just what is distinctive about legal as opposed to other social rules can only be understood in terms of historical and social facts in which Hart shows surprisingly little interest. Notwithstanding these criticisms, there is strong reason to think that Hart's work has real significance for the social sciences.

First, in reviving the tradition of descriptive legal theory – the attempt to provide a systematic elucidation of law – Hart illuminated an institution whose distinctive importance in the organization of modern societies has become a fundamental preoccupation of the social sciences. In spite of his universalistic philosophical ambitions, and of the undoubted tension in his work between his analytic and his descriptively sociological methods, his theory can be argued to provide a persuasive account of the distinctive nature of legal authority – law's normativity – while maintaining that law's existence is, ultimately, a matter of social fact and hence susceptible to empirical inquiry.

Second, therefore, in elucidating the nature of law as a social institution, Hart arguably provides precisely the sort of legal theory which social scientists need in incorporating law into broader social analyzes (Sugarman, 2005). In his insistence on the structural continuity between legal and other social rules yet on law's distinctive mode of institutionalization, Hart provides a vision that is at once analytically well delineated yet relatively modest in terms of its substantive assumptions. Hence, the feature of his theory that might at first sight seem least sympathetic from a social science point of view – its pretension to provide a universal theory of law – may in fact be argued to be one of its strengths, for it provides a clear model for the purposes of testing hypotheses about, for example, the relationship between legal and other forms of social authority. This idea of his concept of law as, at root, a social science model is backed up by his own insistence, in terms reminiscent of Weber (though, in a significant ambiguity, also of Aristotle), that he is delineating a central case with reference to which other, penumbral cases can be identified and analyzed rather than banished to another discipline.

Third, in his insistence on the internal aspect of rules, and hence on the idea that the social phenomenon of law can only be understood by reference to the attitudes and understandings of the agents who are its subjects, Hart's thinking meshed with a cluster of theoretical developments in disciplines such as sociology and anthropology. In this respect, his theory is a vast step forward from the cruder empiricism of the nineteenth-century positivists. Although it is not something with which Hart himself was centrally concerned, this feature of his method undoubtedly opens up the possibility of an analysis of the symbolic aspects of legal power and authority such as would be central to any adequate social science account of legal practices. In his emphasis on the importance of linguistic usage, moreover, his ideas relate, albeit obliquely, to the so-called 'linguistic turn' in much social theory of the late twentieth century.

Finally, in his revival of the utilitarian tradition of systematic critique of law and argument for its reform, Hart provided an example of the way in which conceptual analysis can be marshaled in aid of social policy. Clear thinking and

reason – Hart's deepest intellectual commitments – are used, in an apparently modest and sometimes painstaking way, to clear the confusion in social and political debate, opening up in often unexpected ways paths forward in the development of policy and the construction of social consensus. Though Hart's own work is surprisingly little concerned with empirical – social, psychological, economic – evidence, his arguments often serve to clarify the relevance of just this sort of social science data. Though the fulcrum of his work lay firmly at the analytical-philosophic rather than the descriptive-sociological end of the spectrum, he can, therefore, justly claim a place among those whose thinking has made a significant contribution to the social and behavioral sciences.

Abstract

The term 'hate crime' has been frequently applied not only by media and government representatives, but also by social scientists, to characterize attacks based on race and religion, but also on sexual orientation, national origin, disability status, and gender. Hate crime statutes vary from state to state. Since 2009, a federal law lends some consistency to the protected groups covered by hate crime laws. The majority of hate crimes are committed by dabblers – individuals who attack on a part-time basis and lack any affiliation with organized hate groups. Some commit hate offenses for thrill; others believe they are being defensive. Still others retaliate for an offense initially perpetrated by a member of another groups. Few are on a mission to rid the world of evil, as they see it. Hate crimes against particular groups tend to rise and fall in response to the presence of perceived threats.

Hate crimes are criminal offenses motivated at least in part by the fact or perception that a victim is different from the perpetrator. The term has been employed since the late 1980s, when it was first applied by journalists and politicians to characterize a racial incident in the Howard Beach section of New York City. In this incident, an African-American man was killed when he attempted to evade a violent mob of teenagers shouting racial epithets. By the early 1990s, the hate crime designation was being applied not only by media and government representatives, but also by social scientists, to characterize attacks based not only on race and religion, but also on sexual orientation, national origin, disability status, and gender (Herek and Berrill, 1992; Levin and McDevitt, 1993).

As used by the FBI and a number of other law enforcement agencies across the United States, the term hate crime involves a behavior that has already been defined as illegal in state or federal statutes. Thus, the majority of hate crime laws do not criminalize any new behavior; instead, they increase the penalty for behaviors that are already against the law. In addition, this definition specifies the motivation for committing the offense; it requires that a racial, religious, ethnic, or some other identified characteristic of the victim plays at least some role with respect to inspiring an attack.

Although widely used by the federal government, the media, and researchers in the field, the term 'hate crimes' is somewhat misleading because it suggests incorrectly that hatred is invariably a distinguishing characteristic of this type of offense (Perry, 2003). While it is true that many hate crimes involve intense animosity toward the victim, many others do not. Conversely, many crimes involving hatred between the offender and the victim are not hate crimes in the sense intended here. For example, an assault that arises out of a dispute between two coworkers who compete for a promotion might involve intense hatred, even though not based on any racial or religious differences between them. Similarly, a love triangle resulting in manslaughter may provoke intense emotion, but may have nothing at all to do with race or religion. After decades, however, the term hate crime has become a widely recognized and accepted part of our vernacular as well as the social scientific literature and legislation across the country. Notwithstanding its problematic aspects, those who study the phenomenon have continued to use the term as a basis for what appears to be an ever-expanding literature. In the early 1990s, for example, only a book or two were entitled 'Hate Crimes' (including a work written by the authors of this article); by the turn of the century, there were at least 30 scholarly volumes bearing this title and many more on the way.

Legal Distinctions

In legal terms, the groups protected by hate crime laws have traditionally differed from state to state. Almost every state – at least 45 out of 50 – protects victims who are targeted because of their race, ethnicity, or religion, but far fewer cover sexual orientation (25 out of 50), disability status (22 out of 50), or gender (21 out of 50). The implication of this lack of uniformity is that members of a particular group may be protected by a hate crime statute in one community but not protected in a neighboring community in an adjacent state (Smith and Foley, 2010).

One of the early pieces of federal legislation regarding hate crimes, the Hate Crime Sentencing Enhancement Act, was passed in 1994. This statute increased sentencing penalties in federal cases with proof of victim targeting based on race, color, religion, national origin, ethnicity, gender, disability, or sexual orientation (Cogan, 2002; Levin, 2002). Also in 1994, the Violence Against Women Act was passed allowing for punishment and compensation in relation to federal crimes motivated by gender and promoting the inclusion of gender in the definition of hate crimes in a number of states (Grattet and Jenness, 2001).

In 2009, a greater degree of consistency among the 50 states was achieved by the expansion of a federal hate crimes statute known as the Matthew Shepard and James Byrd, Jr. Hate Crime Prevention Act, which supported federal prosecution of offenses based not only on race, religion, and national origin

but also on sexual orientation, gender, gender identity, and disability status. Based on the 2009 federal law, even where a particular category is not protected at the state level, federal officials can now move to support the prosecution of a hate crime charge. It also makes grants available to communities in order to train law enforcement officers or assist in their investigations and prosecutions of bias-motivated offenses.

A second area of legal distinction involves the penalty structure of the statute. In some states, a separate statute exists that prohibits hate crime behavior. In other states the hate crime statute is a 'penalty enhancement.' This means that if an existing crime is committed and it is motivated by bias, the penalty on the existing crime may be increased. Penalty enhancements have been applied not only to hate crimes, but to other offenses as well. For example, they have been enacted in connection with crimes committed with a gun, crimes committed by individuals with long criminal histories, and crimes committed against vulnerable victims such as children.

A number of critics of hate crime legislation have suggested that the kinds of legislation described above are an unconstitutional infringement on our freedom of speech. The US Supreme Court has been careful to protect free speech; but in 1993 (Wisconsin vs Mitchell), the Court decided that statutes that enhance the criminal penalty due to the bias motivation of the offender were constitutional.

Do Hate Crimes Really Differ from Other Offenses?

The question is frequently posed as to why we need additional penalties in response to hate offenses. After all, hate crimes by definition involve behavior – for example, assaults, threats, and vandalism – that is already prohibited by state or federal statute. It is therefore important to ask: Are hate crimes truly different?

We believe that a number of characteristics of hate incidents make them different from other types of offenses. First, hate crimes are directed symbolically at large groups of people, not only at a single individual. If youths decide that they do not want Asian-Americans living on their block, they may decide to throw a rock through the window of a home owned by a new neighbor who is of Asian descent. Their intention is to send a message not just to that neighbor but to all Asians, informing them that their presence in the neighborhood will not be tolerated.

Thus, not unlike acts of terrorism, hate crimes are frequently about transmitting messages. Offenders use a criminal event to put the members of an entire group on notice, by example, that they are not welcome in a community, in a workplace, on a college campus, or at school. By contrast, if a window is broken in a simple act of vandalism, the offenders typically have no desire to communicate anything in particular to the property owner; in general, they are totally unfamiliar with the victim they have targeted.

Another characteristic that differentiates hate crimes from most other offenses is that the victim characteristic motivating the attack (e.g., race or ethnicity) is in most cases ascribed and immutable. A person cannot simply choose to modify her or his race, ethnicity, age, or disability status. Even a religious identity or a sexual orientation cannot be changed without causing an individual to make dramatic and painful modifications in lifestyle. Consequently, if a woman is attacked because she is a Latina, there is little that individual can do to become 'de-Latinized' and thus reduce the likelihood of her future victimization. This is also true of perceived characteristics. If a man becomes a hate crime victim because he is perceived by a group of youths to be gay, he is also powerless to change the offenders' perception of him. The feeling on the part of victims that they lack control over the characteristic that motivated their victimization causes most hate crime victims to feel extremely vulnerable to future bias-motivated attacks.

A third characteristic of hate crimes that makes them different from many other offenses is that the individual victim typically did nothing in particular to precipitate the attack and is therefore interchangeable, at least from the perpetrator's standpoint. To a group of youths waiting outside a gay bar to attack someone whom they believe might be gay, it does not matter which individual is next to pass through the door. Whoever comes out is likely to become a victim, because all bar patrons are identical in the mind of the perpetrator.

Indeed, the interchangeability of victims tends to apply as well across various groups of victims. If offenders cannot locate the members of one racial group to terrorize, they are likely to target members of another racial group. This aspect of hate crimes suggests that they are often motivated by an offender's psychological need to feel superiority at the expense of his victims. Particular characteristics of victims are apparently less important conceptually than the motivation of offenders who, out of a profound sense of powerlessness, decide to attack victims who have been stereotypically defined in the dominant culture as inferior or evil.

A fourth characteristic that separates hate crimes from many other offenses involves the severity of their outcome. Research suggests that victims of hate crimes are more likely to experience intrusive thoughts, depression, anxiety, and Posttraumatic Stress Disorder (PTSD) when compared to victims of nonbias crimes (McDevitt et al., 2001).

Problems Collecting Hate Crime Data

During the 1980s researchers, journalists, and government officials increasingly turned their attention to questions regarding the extent and nature of hate crimes in the United States. At that time there were no national data gathered on the incidence and character of such offenses. The FBI, the agency responsible for collecting and reporting national data on crime, did not collect information separately for offenses motivated by bias. For example, a hate-motivated assault reported by the local police to the FBI would be grouped together with other assaults, regardless of their motivation. As a result, it was impossible to distinguish which offenses were hate-motivated and which were not.

In April 1990, Congress passed and the President signed the Hate Crime Statistics Act (28 USC 534). Although not criminalizing any particular behavior, the Act required the Attorney General of the United States to publish an annual report about crimes that 'manifest evidence of bias based upon race, religion, sexual orientation, or ethnicity.' This act authorized the first national data collection effort undertaken by any public

agency to be targeted specifically at hate crimes. The Uniform Crime Reporting (UCR) Section of the FBI was designated as the federal agency empowered to collect and tabulate these data. In September 1994, the Hate Crime Statistics Act was amended to include bias against persons with disabilities by passing the Violent Crime Control and Law Enforcement Act of 1994. The FBI began collecting data for the additional bias type on 1 January 1997.

Although mandating the Attorney General with the responsibility for gathering information and publishing an annual report about hate crimes, the Hate Crime Statistics Act did not require that local law enforcement agencies report to the FBI. Historically, crime reporting has been voluntary with most but not all major law enforcement agencies agreeing to participate.

Hate crime reporting was initially a different story. Many agencies had not separated hate crime data from other offenses in their collection procedures. As a result, retrieving these data was not an easy task. In addition, many law enforcement agencies resisted the new national emphasis on hate crime investigation. For these reasons, few agencies participated in the original effort. In 1991, 2771 agencies submitted hate crime data to the FBI, which represented only 20% of the agencies participating in the UCR program. As a result of significant training efforts of the UCR Section of the FBI and effective support from local advocacy groups, however, the participation rate by 2011 had increased to 14 575 agencies representing approximately 80% of all agencies submitting information to the FBI.

These improved participation figures may not, however, be as positive as they appear. According to the Department of Justice, two out of three hate crimes go unreported. Estimates of the prevalence of hate crimes vary substantially from 7000 to 8000 annually, as reported by police jurisdictions to the FBI, to some 200 000 yearly, as reported anonymously by victims to the Department of Justice. Part of the reason for such a wide disparity involves the lack of responsiveness to hate crime victims by numerous police agencies, where hate attacks are simply unreported. Moreover, relatively few hate-motivated offenses are ever prosecuted. Even fewer result in a conviction. One of the problems moving from arrest to conviction involves the large number of cases that are dismissed based on the lack of cooperation of victims and/or eyewitnesses, or cases where the prosecutors refuse to indict because they feel they do not have adequate evidence of bias motivation.

The FBI program allows agencies to submit zero as their total count of hate crimes. According to a recent FBI report, nearly 87% of participating agencies report no hate crimes occurring in their jurisdiction during the previous 12 months. While reporting zero hate crimes may accurately reflect the number of hate crimes in many jurisdictions, scholars suggest that some agencies, particularly in larger and more diverse communities, are not fully and accurately collecting information on and reporting hate crimes (McDevitt et al., 2003). In 2011, for example, three states reported fewer than six hate crimes: Mississippi (1), Wyoming (2), and Louisiana (5). Similarly, a number of major cities reported surprisingly small numbers of hate offenses, such as Detroit, Michigan (7); Cleveland, Ohio (4); Atlanta, Georgia (2); St. Louis, Missouri (7); and Houston, Texas (13). Over the same period, Boston reported some 206 hate crimes (FBI, 2012).

Also contributing to what appears to be a vast underestimate in FBI statistics is the unwillingness of victims to make official reports. They may see law enforcement as 'the enemy of occupation,' based on traditional antagonisms between the police and people of color or gay and lesbian residents. Or, if they have migrated from certain other countries, they may consider law enforcement as associated with a tyrannical regime. People with psychiatric or intellectual disabilities may not totally understand the process of reporting hate-motivated attacks and may instead suffer in silence.

Another problem involves indicators for identifying the motivation of an offender. In many cases, the most obvious measures consist of slurs, epithets, or graffiti left by the perpetrator at the crime scene. In addition, police investigators may look for a suspect's criminal record, a location where previous hate attacks have occurred, and evidence that the suspect holds membership in an organized hate group. Obviously, not all offenders leave evidence of their motivation; many are first offenders who lack a criminal record and are dabblers in hate. In many cases, the use of slurs is the only indicator available, causing a court battle of 'he said, she said' between victims and offenders.

Types of Hate Crimes

In terms of offender motivation, hate crimes have been categorized into four major types (Levin and McDevitt, 2002; McDevitt et al., 2002): (1) *thrill*, which are almost recreational attacks committed by youngsters – usually groups of teenagers or young adults – who seek excitement as well as 'bragging rights' with their friends; (2) *defensive*, which are designed to protect an individual's neighborhood, workplace, school, or women from those who are considered to be outsiders or intruders; (3) *retaliatory*, which are motivated by an individual's need for revenge as a result of a hate attack directed against his or her own group members; and (4) *mission*, which are rare and usually committed by the members of an organized hate group or an offender who suffers from a severe mental illness (e.g., psychosis). This typology has become part of the National Hate Crime Training Curriculum and is taught in the FBI Training Academy in Quantico, Virginia.

The majority of hate crimes are committed by dabblers – individuals who attack on a part-time basis and lack any affiliation with organized hate groups. They might go out with their friends on a Saturday night looking for a vulnerable victim to bash. Or, they might send a threatening message to a new resident of their neighborhood, informing them that 'their kind' is not welcome. Actually, no more than 5% of all hate crimes nationally are committed by the members of organizations like the Ku Klux Klan, Aryan Nations, or the Hammerhead Skins. Yet through their presence on the Internet, organized hate groups continue behind the scenes to support much larger numbers of violent offenses committed by nonmembers who may be unsophisticated with respect to the ideology of hate, but are looking to feel important and a sense of belonging. Not only do such groups provide angry and isolated youngsters with effective propaganda but they

also generate chat rooms and discussion boards, where recruits develop newfound friendships with like-minded hatemongers.

A brutal example of the influence of hate groups on the Internet involves the January 2009 murder of two Cape Verdean individuals and the rape of a third in Brockton, Massachusetts, by 22-year-old Keith Luke who was not a member of any organized hate group but was clearly looking for a scapegoat on whom he could blame all of his personal miseries. Unemployed, friendless, and suffering from chronic mental illness, Luke spent day after day logging into hate Web sites, where he found racist propaganda and numerous opportunities to chat with fellow hatemongers. A few hours after President Obama's first inauguration speech, Luke decided that he had had enough from non-white Americans and went on his bloody rampage. His intended victims also included a nearby synagogue, where he had planned to open fire and kill as many Jews as possible. Instead, he was taken into custody and eventually stood trial. On 30 May 2013, Luke was convicted of first-degree murder and sentenced to life without parole eligibility.

Are Hate Crimes on the Rise?

Though limited to those crimes that are reported to the police, national hate crime statistics provide a critical measure of the prevalence and distribution of hate crimes throughout the country and over time. Between 2000 and 2011, with the exception of a spurt to almost 10 000 hate incidents in the year 2001, the FBI reports the total number of hate-motivated crimes reflected in the national statistics remained relatively constant, ranging from slightly more than 6000 in 2011 to almost 8000 in 2008 (**Figure 1**).

Rather than yield a strong trend over time, hate crimes against particular groups tend to rise and fall in response to the presence of perceived threats (Quillian, 1995; Levin, 2014). In Green's (2001) defended neighborhood hypothesis, hate crimes occur as a defense against neighborhood in-migration of ethnic or racial 'intruders.' This hypothesis can be expanded to include perceived threats to a group's self-esteem, economic well-being, religious or cultural values, sexual identity, or physical survival. In 2001, for example, hate-motivated assaults against Muslim/Arab Americans soared by some 1600%, as many Americans became anxious about their safety from the impact of international terrorism.

Responses to Hate Crimes

Interviews with victims of hate violence indicate that the aftermath of the victimization is characterized by a pervasive feeling of fear. As indicated earlier, the victims of these incidents generally did nothing to bring this violence upon them and thus do not know what to do to reduce their chance of future victimization. Their fear may be based on threats by the offender or friends of the offender but often it is simply based on the random nature of the crime (McDevitt et al., 2001). In addition, the fear is felt by many others who may share characteristics with the victim.

In order to reduce fear in victims of hate crimes, it is important to offer them some form of protection from future violence and a degree of reassurance that they are valued members of the community. First of all, community leaders must speak out, condemning the attack. This is important because it sends two essential messages: to the victims, that local residents want them to remain members of that community and, to the offenders, that most people in the community do not support their illegal behavior. This speaking out should be done on two levels: one, a public event such as a vigil; and second, individual conversations with the victim and the victim's family where questions can be answered and personal assurances be conveyed.

Interviews with hate crime offenders indicate that they frequently fear that most of the community shares their desire to eliminate the 'outsider.' The offenders often see themselves as heroes or at least as 'cool' in the eyes of their friends, because they have the courage to act on what they believe to be commonly held beliefs. Public statements by local community leaders challenge this idea and send a message to offenders that their actions are not supported or encouraged.

Many hate crimes are perpetrated by young people who do not yet have a profound commitment to bigotry and therefore may be dissuaded from repeating their offense. It is important, therefore, to apprehend youthful hate crime perpetrators at this point, especially in light of the possibility that many property offenders who go undetected may later graduate to more violent hate crimes directed against people. Because what the perpetrators derive from committing such crimes is so minimal in a practical sense, they may be very deterred by a strong statement from society at large that demonstrates that this type of behavior will not be tolerated and a fear that they could be arrested and brought into the justice system. There is evidence that the police and the courts (not to mention public opinion) may have become much tougher on youthful hate crime offenders during the past several years.

The local police play an essential role in responding to hate crimes. Advocacy groups can offer support and encouragement, and political leaders can offer reassurance, but the police represent the only group that can legitimately promise to protect the victim from any future attack. Since so many victims are extremely fearful of future attacks, this offer of protection is so important. Before law enforcement personnel can effectively offer this protection to victims of hate crimes, however, they must be trained to identify and investigate these difficult cases. The UCR Section of the FBI has developed an outstanding training program for local law enforcement that teaches officers how to identify and effectively prosecute hate crimes.

In order for police to effectively support hate crime victims, as indicated above, it is helpful if they have training in what hate crimes are and how victims generally respond. Additionally, for many victim groups (e.g., Muslim or Middle Eastern victims or members of the Lesbian, Gay, Bi-sexual, Transgender, Questioning (LGBTQ) community) it is very important that police make outreach efforts before a hate crime occurs and begin to develop relationships in the community so that victims will feel comfortable coming forward to the police and asking for help. Hate crime victims are often ambivalent about the value of law enforcement and do not necessarily see a police officer as someone they can go to for help.

Finally, the most important response to a hate crime, as reported by its victims, is the reaction of those closest to them – their neighbors, coworkers, or fellow students. When a hate crime occurs, victims quite realistically wonder just how widespread is the hatred directed toward them. Do all their neighbors agree with the person who attacked them? Do all of their classmates want them to leave school? Therefore, the most significant reaction for most victims is when members of the perpetrator's group come forward to assure the victim that they do not agree with the offenders and to urge the victims to remain in the neighborhood, the workplace, or the campus.

Hazards and Disaster Research in Contemporary Anthropology

Abstract

Disasters are highly complex, multidimensional processes and events that take place in both the material and social worlds. It is in this multidimensionality of disasters that the salience of anthropological theory and application manifests itself most clearly. The holistic perspective of anthropology is ideally suited to address the multifaceted realities of disasters. As disasters develop and occur, all dimensions of a social structural formation and the totality of its relations with the total environment become involved, affected, and focused in patterns of vulnerability and resilience over time. In disasters are expressed continuity and change, cooperation and conflict, power and resistance, all articulated through the operation of physical, biological, and social systems and their interaction among populations, institutions, and practices. Mining this rich vein of thought and behavior that disasters bring into intense focus, presents not only a challenge but an important opportunity to probe the multiple linkages and relationships they reveal for sociocultural theory and, by the same token, establish what anthropology can offer to the study of disaster both in the realm of research as well as the practice of disaster management.

Introduction

Disasters, in their origins and outcomes, are highly complex, multidimensional processes and events that take place in both the material and social worlds. In that sense, disaster research is inherently multidisciplinary and anthropology shares many perspectives with other social sciences, in particular geography and sociology. However, the holistic approach of anthropology is ideally suited to address the multifaceted realities of disasters. From this perspective, a disaster is a process/event involving the combination of a potentially destructive agent(s) from the natural, modified, and/or constructed environment and a population in a socially and economically produced condition of vulnerability, resulting in a perceived disruption of the customary relative satisfactions of individual and social needs for physical survival, social order, and cultural coherence.

A disaster is a collectivity of intersecting processes and events, environmental, social, cultural, political, economic, physical, technological, transpiring over varying lengths of time. Disasters vary from sudden to rapid onset events such as earthquakes, tornadoes, hurricanes, tsunamis, floods, technological accidents, and terrorist attacks to slower onset processes such as droughts, heat waves, epidemics, famines, toxic exposures, and frosts. Many of these events/processes will also vary, sometimes according to the available predictive technology, as to the degree of warning and preparation a society may have before onset. However, as they occur and unfold, all dimensions of a society and the totality of its relations with the environment may become involved, affected, and focused, expressing consistency and inconsistency, coherence and contradiction, cooperation and conflict, hegemony and resistance, expressed through the operation of physical, biological, and social systems and their interaction among populations, groups, institutions, and practices. Like few other phenomena the multidimensionality of disasters forces us to confront the many and shifting faces of socially constructed reality(ies).

As events and processes, hazards and disasters are totalizing phenomena, subsuming culture, society, and environment together. Anthropology as a discipline embraces in its substantive platform the physical, biological, and social aspects of human existence. It includes developmental and comparative perspectives. Anthropology frames specifics against larger wholes and examines issues of social change and evolution. With the holistic perspective that is the hallmark of the field, anthropology employs a theoretical framework that can encompass the entire scope of disaster causation and impact, even for the analysis of the essentially novel conditions that emerged in human–environment relations in the latter half of the twentieth century. In addition, disasters present anthropology with important contexts to test key theoretical formulations regarding such themes as social organization, the moral economy–political economy question, and human–environment relations.

Although anthropologists occasionally studied disasters since its post–World War II emergence as a research field, only in the last 25 years have disasters actually become a significant focus for anthropological research. However, a number of anthropologists were among the earliest contributors when the field emerged in the 1950s. Early anthropological studies generally occurred because anthropologists were examining other issues in places that had experienced disasters. Moreover, prior to 1970 these studies constituted the only disaster research, anthropological or otherwise, in the developing world. The field of disaster research in general was entirely focused on European and North American events, where anthropologists did not generally study, with the notable exception of the lasting contribution of Anthony F.C. Wallace's research on a tornado in Worcester, Massachusetts tornado from which he developed his spatial/temporal framework for disaster events (1956) that still informs much disaster research today.

As social scientific disaster research began to expand in the 1950s, anthropological participation remained low, due largely to a particularist and functionalist emphasis on the construction of cultural profiles based on the ethnography of "normal, daily" life that precluded addressing the issues of disruption and change that disasters represented. Much disaster research, including anthropological studies along with other fields such

 http://dx.doi.org/10.1016/B978-0-08-097086-8.12188-9

as sociology and geography, tended to focus around the event in both space and time.

The reemergence of interest in sociocultural change, development (and underdevelopment), and cultural ecology in the 1960s, however, created a set of theoretical fields that would eventually encourage and enable anthropologists to engage with the issue of disasters in the 1970s. In effect, these emerging theoretical concerns addressing issues of human environmental adaptation in the past or present required a consideration of the interaction of the social, technological, and natural processes of change and human welfare that revealed the importance of hazards and disasters (Torry, 1979).

A Paradigm Shift

The decade from the mid 1970s to the mid 1980s marks a watershed in disaster research generally, and in the anthropological study of disasters specifically, with the emergence of two concepts that drove a paradigmatic change. One of these concepts, vulnerability, emerged from disaster research itself and the other, resilience, saw its origins in the field of ecology, which in turn had drawn from engineering and physics. Both concepts required greater scrutiny of the underlying causes of both disaster loss and damage and are also complexly intertwined with the questions of adaptation and development. Indeed, both concepts are foundational for important advances in our understanding of disasters in anthropology and in the other social sciences. Importantly, the shifts in perspective toward vulnerability analysis occurred in the same time frame as a number of large disasters in the developing world, such as the Peruvian earthquake (1970), the Guatemalan earthquake (1976), and the Bangladesh flood (1987) and increased media coverage of these events. Furthermore, there was greater appreciation by anthropologists that major events were interspersed with other innumerable deadly events of sometimes only slightly lesser magnitude that were occurring in the nations and regions where they were working. Depending on the definition of disaster, many anthropologists also began to discover that the societies they were studying were actually, in one form or another, postdisaster societies (Oliver-Smith and Hoffman, 1998).

The concept of vulnerability focused attention on those aspects of society that reduce or exacerbate the impact of a hazard. Basically, anthropologists and cultural geographers working in the developing world found that mainstream disaster studies brought little of value to the task of analyzing disasters in Third World contexts. These researchers criticized the essentially passive role prior investigators had assigned to society in risk etiology and the scant attention paid to local, national, and international factors in creating or exacerbating both risk and impact. They called for a rethinking of disasters from a political economic perspective, based on the high correlation between disaster proneness, chronic malnutrition, low income, and famine potential, leading to the conclusion that the root causes of disasters lay more in socially constructed conditions of vulnerability than in nature (O'Keefe et al., 1976; Hewitt, 1983). The work of the Network for Social Research on Disaster Prevention in Latin America, known as La RED, particularly contributed to the expansion of the vulnerability-risk perspective beyond the Euro-American context (Lavell, 1994). Vulnerability, soon generally called social vulnerability, refers to those characteristics of a society that render its members subject to harm and loss in a disaster. Vulnerability expresses the multidimensionality of disasters by focusing attention on the totality of relationships in a given social situation into the formation of a condition that, in combination with environmental forces, produces a disaster.

Moreover, because vulnerability was most intense in the developing world, where most anthropologists worked, they and other social scientists began to draw an association between disasters and development, or underdevelopment. The enormous disparities in deaths and losses between disasters in the developed and developing worlds thus identified high disaster mortality and destruction as features of underdevelopment. This is, in essence, a political ecology of disasters. Factors such as the lack of access to resources, lack of political power and representation, inadequate housing and infrastructure, poor sanitary conditions, lack of access to education and health care, and density of settlement, all these characteristics of underdevelopment, have been cited as most frequently associated with high vulnerability (Wisner et al., 2004).

At roughly the same time, ecological anthropologists concerned with advancing the field of cultural ecology urged researchers to focus on hazards from an ecological and social organizational perspective (Vayda and McKay, 1975). Ecological science itself also began moving away from the idea of ecosystems as static entities in equilibrium toward systems in which change is normal, asserting that disturbances actually increase the chances that a given ecological system will not return to a former state, but will nonetheless persist. In other words, it is resilient (Holling, 1973). The concept of resilience refers to "the capacity of an eco-system to undergo disturbance and maintain its functions and controls and may be measured by the magnitude of disturbance the system can tolerate and still persist" (Wallington et al., 2005: 15).

Social scientists soon saw the application of the concept to society, framing resilience as the ability of social groups or individuals to bear or absorb sudden or slow changes and variation without collapsing is social resilience (Holling and Meffe, 1996). Indeed, Holling argues that this stream of research "… has the most natural connection to related ones in the social sciences that are historical, analytical, and integrative. It is also the stream that is most relevant for the needs of policy and politics" (1993: 553). Like vulnerability, resilience is a function of social organizational features that govern the interaction of human systems and the natural world. Basically, resilience refers to the ability to prepare and plan for, absorb, recover from or more successfully adapt to actual or potential adverse events (National Research Council, 2012). Rather than the opposite of vulnerability, resilience interacts dialectically with vulnerability in the form of dynamic adaptations to environmental and social processes in moving from disaster risk reduction to sustainability (Aguirre, 2007).

In this view, community resilience is a constantly evolving process of learning and adaptation to new knowledge,

information that is dialectically related to disaster risks and emerging vulnerabilities. Disaster resilience may also be framed as both an outcome and a process where there are inherent vulnerabilities and resiliencies in the community prior to an event and these influence the ability of the community to absorb the impacts, which result in either rapid or slow post-disaster recovery. Therefore there are constant feedbacks between vulnerabilities and resiliencies such as preparedness and disaster mitigation activities, as well as social learning that occur as a means for enhancing resilience over longer time frames (Cutter and Morath, 2013).

Both vulnerability and resilience to hazards are complex and multidimensional as are the specific social contexts and conditions they express and reflect. As the resilience and the social vulnerability perspectives have developed, both generated similar policy relevant paths. Both fields of inquiry internalized and "routinized" risk and disturbance. Both emphasized the centrality of interactions across temporal and spatial scales, particularly the importance of historical analysis in assessing current conditions. Finally, both vulnerability and resilience required a new perspective on the relationship between society and environment. In effect, with the concepts of vulnerability and resilience both the social and the natural sciences moved from environment and society as a duality to a more mutually constitutive relationship. This mutual constitution becomes abundantly clear in the context of disasters and even more so with climate change. Thus, in this understanding, people are not just vulnerable to hazards, but hazards are increasingly the result of human activity, not just technologically, but in terms of human alteration, or construction of the environment. Disasters more than ever now express and energize most clearly that mutuality (Oliver-Smith, 2002).

This more complex understanding of vulnerability enables researchers to conceptualize how social systems generate the conditions that place different kinds of people, often differentiated along axes of class, race, ethnic, gender, or age, at different levels of risk from the same hazard and suffering from the same event. By incorporating specific political, economic, and social variables in combination with specific environmental features, the cause of disasters is situated in the interface of society and environment.

Disasters, no matter how large, are experienced first at the local level. Even an enormous disaster affecting great areas and legions of people, while it may result from a single climatological, geological, or technological phenomenon, ultimately comes down to a compendium of local but related disasters experienced throughout the region and numbers affected. Not all communities experience a disaster in the same way or to the same degree. Each community undergoes a catastrophe in the context of its culture, social structure, and profile of vulnerability. The fact that vulnerability is unequally distributed means that the same disaster agent will show great variation in both patterns of destruction as well as interpretation of cause, effect, and responsibility. It sharpens our understanding of disasters as the outcomes of specific features of systems, social and otherwise. In colloquial terms, it makes it clear that disasters just do not happen. They are features, characteristics of systems of social and material relations, albeit very complex systems.

Complexity, Risk, and Disaster in Contemporary Anthropological Perspective

As we enter the second decade of the twenty-first century, anthropological disaster research, and the field of disaster research in general, is in flux, grappling with increasing levels of vulnerability among increasing populations in many areas of the globe. Debates are active around such issues as the role of culture in disaster vulnerability and resilience, the concepts of coping and adaptation, the role of development in driving disaster risk, and the interface between disasters and climate change. While natural and technological sciences are advancing understanding of hazards significantly, the major challenges for disaster risk reduction are found in the domains addressed by the social sciences. Anthropological disaster research is confronting these challenges, sharing a variety of perspectives and methods with other social sciences. While anthropology in general has adopted some quantitative methods, there is now a broad social scientific recognition that ethnographic methods are extremely effective in capturing the processual dimensions of disaster vulnerability, disaster events, and postdisaster processes of recovery.

The salient characteristics of anthropological research on disasters continue to be longitudinal and processual, oriented by a recognition that disasters involve far more than catastrophic events. They are recognized as processes that unfold through time and their beginnings are deeply embedded in societal history. These concerns relate directly to the relationship between humans and nature and possible strategies for more sustainable forms of development. The anthropological focus has contributed to a shift from an exclusive focus on the disaster site to greater attention to the multiple sites where both policies and practices are developed as well as outcomes play themselves out. Therefore, anthropological disaster research focuses not solely on space and time, but on the social construction of risk and vulnerability, perhaps driven by nonlocal forces, that historically preceded the event, the event(s), and the operative social relations among individuals and groups, both formal and informal, through the various stages of impact, emergency, relief, and reconstruction. There is also an emphasis on the role of social relations and cultural orientations, knowledge, values, norms, and beliefs as they are reestablished, reinvented, renegotiated, discarded, or renewed in the process of recovery. Today other social sciences have adopted theoretical approaches and methodologies that are at least partially informed by the anthropological perspectives on culture, society, and the environment.

A number of current trends would appear to indicate that, indeed, an increase in impact and scope of hazards and resulting disasters, already complex and multidimensional, is taking place through combined effects of economic, social, demographic, ideological, and technological factors, that are compounding their complexity many times over. Greater numbers of people are more vulnerable to natural hazards than ever before, due in part to increases in population, but more so, to their location in dangerous areas. We have also created new forms of disaster agents and new vulnerabilities. Indeed, each new advance in technology brings with it a set of risks and vulnerabilities framed by its potential failure. Today, the creation of completely new technologies, whose mere

implementation, regardless of potential or actual malfunction, has had profound environmental and, in some cases, catastrophic impacts. Moreover, global climate change is now recognized as a major threat to human welfare and security that must be addressed both locally and globally. Essentially, it is now predicted that if we continue to use fossil fuels as usual and do not reduce carbon emissions, the eventual outcome may be something similar to that which earth experienced during the time of mass extinctions.

Although its relevance to daily realities in the developing world is debatable, Beck (1992) has referred to the cultural milieu emerging from the recognition of this potential as a globalized 'risk society,' largely to characterize a western society preoccupied with environmental degradation and the threats it represents for terrestrial life.

Anthropological Research on Hazards and Disasters in the Twenty-First Century

Anthropological research encompasses the full spectrum of social research on disaster complexity, vulnerability, warning, impacts, humanitarian aid, recovery, and reconstruction. Certainly, the research tradition of the years prior to the paradigm shift, focusing on individual and organizational behavioral responses, power relationships, economic impacts, and patterns of persistence and change, has continued. Since the paradigm shift anthropological research has acquired a number of different trajectories. However, to give full scope to current anthropological research on disasters is well beyond the available space for this article. Nonetheless, several research streams bear mention for their recent contributions.

In the fields of archeology, ethnohistory and historical archeology the anthropological concern with longitudinal analyses has advanced understanding of disasters in many cases deep into history and prehistory. Archeologists have traditionally been contributors to anthropological analyses of disasters. Recent work in the archeology of disasters has shed light on such issues as the capacities of differently organized prehistoric societies to recover, environmental thresholds of past decision-making, paleo-environmental interaction and previous environmental capacities and human effects on environments, cultural evolution and human management of different environments and the role of the past in creating the ethnographic present (Bawden and Reycraft, 2001; Garcia Acosta, 2002). Both prehistoric and historical archeologists, historical ecologists, historians, cultural anthropologists and other historically oriented anthropologists who are concerned with the long term effects of disasters are exploring human ecodynamics operating in different areas and on different time scales. Their objective is to get a better comparative handle on the interaction of climate change, human environmental impacts, and human–human interaction through a long term perspective on sustainability, adaptation, resilience, spread of pathogens, and threshold crossing changes (www.gheahome.org).

The pursuit of root causes over extended periods of time has led anthropology into more intensive analysis of historically embedded and spatially distant forces behind disaster risk and vulnerability, seeking drivers in broader regional and global systems. In a related vein and continuing the trend of political economic analyses of disaster vulnerability and impact, recent anthropological and other publications document the ways in which crises provide opportunities for the penetration of corporate capitalism and the restructuring of societies. These analyses document such resource transfers disguised as disaster reconstruction or mitigation as the post-tsunami relocation of fishermen and the sale of their land to tourist enterprises and the permanent closing of public housing and the transfer of these facilities to private development in New Orleans after Katrina (Gunewardena and Schuller, 2008). This strain of anthropological research focuses on how people are revictimized by general reconstruction initiatives and specific project design that in effect advance elite interests. These studies point to the implementation of the neoliberal project (privatization, trade liberalization, structural adjustment, decreased social spending, etc.) in disaster settings. Indeed, this research discloses the not always hidden subtexts that are conveyed in interactions between aiders and victims, resulting in greater integration into the state and the market, which some would define as fundamental to standard development practice, which is frequently implicated in the construction of disaster risk.

Over the last 10 or 15 years there has been a greater emphasis in anthropology on developing more situated and sophisticated analyses of the complex relations between humanitarian and development assistance actors and the communities they intend to help. These ethnographies focusing on the micro-sociology of relief and reconstruction follow the complex processes of decision-making about project design and implementation among the diverse social actors from the transnational sector and local populations Benadusi et al., 2011). In effect, these ethnographies foreground the analysis of interactions between the world of practitioners, and the values and norms that guide them, and the world of local populations who must contend not only with disasters, but with the sometimes disruptive impacts of assistance programs, not to mention their frequent failure. The uneven record of disaster preparedness, relief, and reconstruction can in some measure be attributed to failure to take into account local contexts, social relations, and values in and through which disasters are experienced and interpreted. Disasters, no matter how large, are experienced first at local level and effective disaster assistance whether through humanitarian emergency relief or longer-term reconstruction must be implemented in ways that empower local people, rather than restoring or exacerbating local inequalities and vulnerabilities.

Among the vulnerable groups that have been identified, the impact on and the role of women in disasters have taken a central role in research and analysis. Prior to 1995, apart from a few pioneer studies, there was little attention to the issue of women, much less gender in general in disasters. Along with the links between disaster and economic or racial/ethnic stratification, researchers also tended to ignore gender, despite the fact that gender divisions pervade all societies and channel access to resources, generally toward men and away from women, making them more subject to hazard risk and more vulnerability to disaster impact (Enarson and Hearn-Morrow, 1998). Because they are often naturalized, gender relations remain implicit. Men and women for the most part act

according to socially defined expectations, which in the context of human security, generally produces a gender-related social vulnerability (Bari, 1998; Hoffman, 1999). The interrelation between environmental risk and social vulnerability foregrounds a focus on gender as an aspect of social vulnerability. Anthropological studies of gender relations in disaster reveal how they impinge on conditions of risk, vulnerability, impact, and the experience of recovery and reconstruction. For example, disaster management is gendered, shaping organization and dynamics of assistance agencies and operations such as the fact that delivery of assistance is often designed for and delivered to male household heads. Research has also focused on women's capacities as well as vulnerabilities, highlighting the fact that the gendered division of labor often makes women both first responders in impact and long-term caregivers in disaster stricken households. However, women are not the only vulnerable group to be considered by anthropological disaster research. The risks and vulnerability of the elderly and children as well as ethnic minorities has also become an important research stream.

Reconstruction remains, along with disaster risk and vulnerability reduction, our most pressing problem in disaster studies. It is also the least studied by any social science discipline. Why that is so is rooted in the challenges that reconstruction presents to researchers, challenges that anthropologists are uniquely prepared to confront. The discipline's foundational research methodology, ethnography, is particularly appropriate for the process of reconstruction because it is a lengthy process in which people must traverse the difficult path between restoration and change (Ensor, 2009). This process of negotiation between what has been destroyed, what is to be reconstituted and what is to be replaced generally involves tensions among diverse interest groups and cultural norms and values. Methods that privilege narrative and observation with researchers present and in dialogue with participants to gather local knowledge and information are far more appropriate for exploring the process of adjustment and recovery than are more synchronic forms of research.

Postdisaster reconstruction is most often approached as a material transfer process rather than a process of social reconstitution. Disasters are complex phenomena and their complexity is refracted into the process of disaster reconstruction. Social recovery is therefore inextricably linked to the recovery of structures and infrastructural elements, ecosystems, organizations and institutions, economic activity, and culture, making recovery a truly holistic process. From the perspective of applied anthropology, the fundamental question to be asked is how reconstruction can address the complex of environmental, economic, and social variables that produce disasters in a way that will be sustainable, reduce vulnerability, and enable people at the household and community level to survive. In other words, the challenge of reconstruction is how to reconstruct and recover without reinstalling the same system that generated the vulnerability in the first place. Reconstruction becomes a test of the capacity of the system to respond to a clear demonstration that human and environmental destruction is deeply rooted in the social and environmental history. Anthropologists have recognized that reconstruction, to be truly transformative, has to address that complex of factors that makes disasters into the horrors that they become. In other words, reconstruction has to recognize and reflect the complexity, and in its policies and practices address the mutuality between society and nature that resides at the core of any disaster. Moreover, there is increasing cross-fertilization between research and practice on disaster induced resettlement and development forced resettlement based on the recognition that both involve a process of reconstruction of community (Cernea and McDowell, 2000).

Nowhere is that mutuality more clearly expressed today than in the challenges presented by global climate change. The reports from the Intergovernmental Panel on Climate Change (IPCC, 2007a,b) affirm that human induced factors are responsible for generating significant increases in temperatures around the world. Among the consequences of this rise in temperature are increases in the rate of sea level rise, increases in glacial, permafrost, Arctic, and Antarctic ice melt, more rainfall in specific regions of the world and worldwide, more severe droughts in tropical and subtropical zones, increases in heat waves, changing ranges and incidences of diseases, and more intense hurricane and cyclone activity. The changes will disrupt lives and destroy property and livelihoods at the local level, principally through loss of ecosystem services, including food, water, fuel, and nutrition, as well as those cultural elements, largely spiritual and/or aesthetic, that sustain communities through expressive links to natural features. In addition, loss of land due to desertification, sea level rise, and displacement will increase local vulnerability and deprive people of viable livelihoods. The increased intensity and frequency of climate based natural disasters also threaten local communities in many coastal regions around the world. With the increase in surface temperature over the last 50 years, the levels of damage from extreme weather events have increased. On a global scale, losses from natural disasters have increased dramatically over the last half century, particularly so since the middle of the 1980s (Munich Re, 1999: 16). Will the impacts of global climate change qualify as disasters? Regardless of how analysts view these processes, it is fairly clear that their outcomes will be seen and felt as disasters by the affected populations (Crate and Nuttall, 2009).

Moreover, loss of ecosystem services, loss of land, and increased and intensified climate events can be said to interact with each other to compound and intensify the effects of all of them. Global climate changes, in addition, also may combine with other factors, such as environmental contamination, to increase food and water stress, enhance hazard risk, and drive people from their homes. The long tradition of anthropological research on local adaptation to environments generally and climates specifically across cultures and over time has lent particular salience to the field for understanding and managing current challenges presented by global climate change (Strauss and Orlove, 2003). All the previously discussed anthropological perspectives and methodologies, including archeology, ethnohistory and ethnography, that bring insight to specific disaster related topics across temporal and spatial scales are equally relevant to understanding climate change driven processes in specific prehistoric, historic, or contemporary communities. Moreover, while the effects of climate change will be manifested globally, the most serious and damaging impacts will be felt in those poorer and lesser developed countries and regions of the world that have least contributed

to the problem and have fewer resources with which to confront the challenges.

From an applied perspective, anthropology can assist local communities to understand the risks associated with climate change impacts, integrate such risks with local knowledge to develop adaptive responses, and also defend their rights and make their needs known in national policy contexts. In effect, climate change will in most cases simply exaggerate the effects and frequencies of existing hazards, which are largely the outcome of reigning patterns of local vulnerability. Indeed, climate change effects will also increase the vulnerability of people to geological and other hazards not related to climate change. Disaster risk reduction must continue to focus on local, national, and international forces that make people vulnerable to events and processes made even more extreme by climate change effects. Thus, both climate change adaptation and disaster risk reduction must be framed and designed to address those social and economic features that render people vulnerable to environmental hazards in general. Climate change adaptation and disaster risk reduction then are related undertakings, and both must address systemic vulnerabilities as well as hazards posed by specific climate change effects as fundamentally development related phenomena (Kelman and Gaillard, 2010; Lavell, 2011). In that sense, the most effective overall policy for both climate change adaptation and disaster risk reduction is addressing the systemic vulnerabilities and reducing inequality. This policy in effect is also entirely consistent with a policy of sustainable development.

As the fundamental concept of the discipline, culture plays a significant role in the anthropological framing of disaster processes in general. As that complex of thought and behavior has enabled human beings to transmit and accumulate knowledge through time, adapt to myriad environments and generate the enormous diversity of the species, culture is the context in which disaster is experienced. Culture is the grid or lens though which we experience and interpret the material world and the world of our experience through time. It is through cultural knowledge, belief, attitudes, that we generate behavior or act. All the material, economic structures that channel our behaviors are ultimately based on, derived from and mediated by culturally based values about life and the world, values about what the relationships should be between human beings and between human beings and the material world. In other words, even physical forces like earthquakes and hurricanes have to be interpreted before they can be responded to. As Hornberg has recently noted, culture is crucial to socioecological processes and relations. It shapes our way of thinking about ecology, economy, and technology and generates our specific kinds of fetishism and consumption, many of which specifically channel the way we inhabit and use our environment (2009: 255).

Although consistently a subtheme of disaster research, the role of culture in disasters has recently gained greater attention among anthropologists, particularly in the way people experience and interpret disaster threat, warning, impact and recovery. A focus on culture reminds us that not all reconstruction is infrastructural nor are all resources material. The role of memory, not only of predisaster systems, but also of public recognition of significance of loss, is also engaged to reveal its links to hegemonic socioeconomic structures. This research tells us that much of recovery is posited on the restoration, not necessarily of a predisaster system but of a system that allows for predictability of the outcome of actions. Recovery then is less about the process of material reconstruction, and more about the way a sense of logic and predictability, always one of the fundamental aspects of culture, is restored. They also tell us that it is crucial to restore a sense of subjective agency and control, not only in confronting the impact of the disaster, but also in dealing with the uncertain living conditions that characterize life prior to the disaster, particularly the lives of the poor in the developing world in general. There has also been a tradition of contributions on the role of religion in the explanation of loss and tragedy, in the development of cultural resilience, and in the reformulation of meaning in the aftermath of disasters (Bode, 1977, 1989; Carter, 2010). In all these studies the importance of ritual and symbol play central roles in the restoration of meaning to life in the aftermath of disasters.

Current approaches frame culture as an array of discourses – essentially a conversation about how life is lived and how it should be lived. It is culture as a dynamic process of production of understandings, as constantly being produced, interpreted, reinterpreted, imposed, and resisted. Society is not generally the organization of completely equitable distribution of resources, but a dynamic arena of contesting interpretations and interests organized along some lines of differentiation, whether they be only age and gender or in more complex situations, color, class, caste, religion, ethnicity, kinship, or any of the other myriad ways that humans have of grouping themselves and distinguishing others as different.

From this perspective, culture is not a single voice, but multiple voices sharing some perspectives, differing in others, all articulating their particular interpretations. Some voices, however, can by virtue of different kinds of power and wealth, come to dominate the conversation. Nowhere is this more apparent than in the conditions of vulnerability and the aftermath of disasters. Everyone in a disaster has a particular perspective and a particular set of interests, perhaps shared with others with whom they share certain characteristics. Thus, disasters are both socially constructed and experienced differently by different groups and individuals, generating multiple interpretations of a complex event/process. A single disaster can fragment into different and conflicting sets of circumstances and interpretations according to the experience and identity of those affected (Hoffman and Oliver-Smith, 2002). The disaster process, evolving through various stages, that while difficult to demarcate exactly for and experienced differently by every affected individual and group, displays characteristic social relations, informed by situated knowledge forms and value systems, among the affected population as well as between the affected population and humanitarian and reconstruction aid agents. That is, different forms of knowledge and different moralities become activated as the character of social relations changes in the evolution of the disaster process.

Disasters almost always bring to the fore tensions in the local cultural scene, the contestation of the different voices in the conversation about what the society should be, between those who want to return to the status quo and those who want

change, between the need to restore the known, the understandable, the familiar and those who want to use the disaster as an opportunity to change society, and many positions along the spectrum between those two perspectives. In effect, disasters can challenge cultural coherence and the integration of society. In some contexts, people come together around shared cultural understandings and goals in a kind of postdisaster social solidarity that nurtures the formation of resilience, and in others, particularly where powerful interests work to reinstate an inequitable status quo, the society is left often more vulnerable than before the disaster. In the final analysis, both vulnerability and resilience are expressions of cultural values about human social relations and how those relations relate to material circumstances.

Conclusion

Disasters focus with great intensity the widest possible variety of intersecting and interpenetrating processes and events of social, environmental, cultural, political, physical, and technological natures, requiring an integrated or holistic analytical perspective for full understanding. In disasters, all dimensions of a society and its relations with the total environment become involved, affected, and magnified, articulated through the operation of physical, biological, and social systems and their interaction among populations, institutions, and practices. There are few contexts in which the mutual constitutionality of the physical and the social are so starkly displayed as in a disaster. Contemporary events have dramatically displayed both long-standing threats and emerging risks and vulnerabilities that need to be confronted. In addition to climate change, research trends now beginning to appear in current anthropological analyses include the interface between critical infrastructures (energy, water, etc) and risk construction, the links between disaster, displacement, migration and resettlement, and the gap between disaster research and practice.

Although the multidimensionality of disasters presents a complex challenge to both researchers and practitioners, anthropologists have found an important opportunity to ask synthetic questions. Mining this rich vein that disasters bring into intense focus, presents not only a challenge but an important opportunity to social science theory as well as practice. Disaster researchers and practitioners need to tackle this multidimensionality and probe the multiple linkages and relationships they reveal for sociocultural theory and, by the same token, establish what anthropology can offer to the study of disaster both in the realm of research as well as practice. It is in this multidimensionality of disasters that the salience of anthropological theory and application manifests itself. It is both appropriate and necessary that theoretical and policy oriented projects in anthropology and the social sciences in general be closely linked. If policies are not based on a solid understanding of human behavior in general and cultural behavior specifically, their success in terms of how they respond to human needs, is jeopardized. By the same token, policy and practice can form the testing ground for theory. In broader terms, then, disaster research constitutes a major theme to address both theory and practice in anthropology.

Hazing in Fraternities and Sororities

Abstract

Hazing in U.S. university fraternal groups is a pernicious and sometimes even deadly practice that dates back to the founding of the first collegiate fraternities in the nineteenth century. In spite of growing antihazing sentiment, laws against hazing in 44 states and campus crackdowns, hazing persists as a rite of passage and tradition in colleges and universities across the United States and around the world. This article examines the roots and manifestations of hazing in university-based fraternities and sororities in the United States. It includes a discussion of university policies and practices to curtail it by national fraternal organizations and antihazing activists. Best practices include the encouragement of bystander intervention to halt hazing as it happens, along with the mandating of alcohol-free (dry) fraternity houses and an end to the pledge period.

Defining Hazing

The number of serious researchers devoted to studying and highlighting hazing is still limited, but the subject is attracting increasing study from social scientists and other academics concerned with trying to end the unabated string of deaths every year from 1970 to 2013 in fraternal chapters, as well as in other clubs and sports teams.

What exactly is hazing? Researcher Aldo Cimino defines the term as "the generation of induction costs (i.e., elements of the experiences necessary to be acknowledged as a 'legitimate' group member) that appear unattributable to group relevant assessments, preparation, or chance." He cites calisthenics being required by a fraternity as an example (Cimino, 2013). Cimino cites automatic accrual theory to explain why higher status fraternities with more and better benefits for a pledge can demand far more severe tests of hazing than a chapter with less status and fewer benefits can expect (Cimino, 2013).

Most higher-education institutions in the United States use the definition of the practice of hazing devised by the Fraternity Executives Association and endorsed by the Fraternal Information and Programming Group, the leading fraternal organization addressing risk-management issues. Hazing is "any action taken or situation created intentionally, whether on or off fraternity premises, to produce mental or physical discomfort, embarrassment, harassment or ridicule" (www.fipg.org). All higher-education institutions and all national and international fraternities and sororities in the United States publish strict policies forbidding hazing. Hazing also meets a definition of bullying if fraternal members put newcomers through tortures intended to make the pledges, neophytes, or associate members quit a chapter, as opposed to the usual hazing methods of putting newcomers through stressful conditions in order to welcome them eventually into the group (Nuwer, 2004).

Early work by Lionel Tiger of Rutgers University promoted the term 'male bonding' and made a case for the evolutionary aspects of hazing from his neo-Darwinian perspective. In 1969, in his book *Men in Groups*, revised in 2004 by Tiger as 'Males Courting Males' in *The Hazing Reader* by Hank Nuwer, he focused on hazing in male fraternities as a means of addressing and explaining some hazing activities he witnessed firsthand at McGill University, a Canadian institution of higher learning. Tiger states that men attracted to higher-status groups, actual or perceived, are attracted in part because they define their own self-image from attractive, higher-status males. In groups such as fraternities that haze (and not all do haze), Tiger states in 'Males Courting Males' that the males staunchly try to defend the status quo by incorporating new members willing to show they are a suitable 'fit' by performing and successfully participating in whatever hazing practices the group deems appropriate and suitable. These practices at the chapter level can be crude, even demeaning, and run counter to what the national or international umbrella fraternal groups may approve. Thus, all the over-the-top practices in a chapter get hidden away in hazing episodes done clandestinely behind closed doors out of sight of advisors and national executive officers.

Tiger, in his 'Males Courting Males' essay, stressed that the ability to consume copious amounts of alcohol in the presence of other fraternal values is a common bonding practice practiced by some fraternities and other high-status male groups such as athletes. In 'Males Courting Males,' he also observes that many fraternal chapters that haze require members to participate in activities that appear homoerotic in nature, requiring pledges alone or in the pledge group to be fully or partially nude during one or more hazing sessions and occasionally assuming submissive poses in front of the poses of dominant senior members. Once initiated, the pledge is given the opportunity to buy a costly ring with the fraternity's Greek letters on the stone, and the ring is worn on the finger traditionally reserved for a wedding ring. There also are pins with the fraternal insignia reserved for females that members find attractive.

Tiger's observations on the need for new fraternal members to achieve a 'clubby' bonding with senior members have echoes in the well-established 'groupthink' theory of researcher Irving Janis (1972). Nuwer (1978, 1999a) adapted Janis' term to 'Greekthink.' The basis for 'groupthink' and 'Greekthink' is that the clubby nature of groups noted by Tiger reflects the overarching quest for camaraderie and a desire for harmonious relationships seen in high-status groups such as fraternities, even rising to a U.S. President's inner circle of advisers and cabinet members, athletes, and so on. Which may not be so

surprising given that the Center for the Study of College Fraternity and Inside Greek U., author Alan DeSantis counts 18 U.S. Presidents since 1877 that claimed fraternity affiliations as collegians.

Janis' term, groupthink neatly sums up fraternal organizations, and their compulsive need and appreciation for camaraderie and the approval of current members and even much older alums whose presence at several hazing incidents in which a pledge died was noted by Nuwer. Groupthink captures the behavior of members performing acts of hazing in a group that prior to joining, they as individuals likely would have dismissed as deplorable. Groupthink also explains why fraternal members can display a delusional belief in their own invincibility while encouraging or ordering hazing activities in order to foster group unanimity. The groupthink theory espoused by Janis also explains the deception, denial, and dishonesty that hazing chapters often demonstrate after a risky practice leading to serious injury or death and an associated investigation. Janis' extensive study in group dynamics further points out that the group's excessive need for solidarity colors the judgment of its members, leading them to approve and carry out activities such as hazing and alcohol overconsumption that, if exposed, can lead to that hazing chapter losing its charter. The cost of losing that charter includes the consequence that the university and its national organization order individual members to disband for anywhere from a year to forever and lose the privileges and status of membership during that ban. Yet, in spite of so much to lose, hazing continues and also continues to attract media coverage and legislative attention.

Because actual acts of hazing are widely different, ranging from beatings to drinking extravaganzas to nude groping and lining up to take verbal abuse, it is difficult to point to a single behavioral cause of hazing. Most hazing researchers refer to 'The Effect of Severity of Initiation on Liking for a Group' by Elliott Aronson and Judson Mills as of crucial value. The two researchers established through experimentation that hazing leads to tighter group solidarity because severe initiation practices cause initiates to appreciate and like the group more than do initiates who are simply invited to join a group without hazinglike demands and sacrifices.

Another often-quoted expert on hazing behavior is James C. Arnold who applied the work on cults by Margaret Thaler Singer, coauthor with Janja Lalich of *Cults in Our Midst*, to fraternities (1995). Arnold asserts in his long essay 'Hazing and Alcohol in a College Fraternity' (in Nuwer's *The Hazing Reader*) that many fraternities fall under the category of 'addictive organizations.' Such groups quite convincingly are compared to individuals obsessed with alcohol, for example, and are similar to a dysfunctional family unit. In short, the chapters that haze use cultlike systematic manipulation and coercion to effect psychological and social influence. In particular, cults and hazing fraternities alike purposely engender enforced dependency by instituting ways and means to make potential members and new members spend the majority of waking and sleeping hours in the company of members and their fellow newcomers. Such organizations promise the new initiates enduring abuse that if they only persist all will be well in the end, and they will experience many rewards once awarded membership when the time of trial expires.

Arnold undertook close participant observation as a doctoral student over a long period of time under the supervision of well-known Indiana University Higher Education Professor George Kuh, also the Director of National Institute for Learning Outcomes Assessment. Arnold on many occasions observed his study chapter perform acts of hazing and alcohol abuse while he performed research for his dissertation in Higher Education at Indiana University that was published in Nuwer's *The Hazing Reader*. He was allowed by the chapter, its national organization, and Indiana University to have nearly complete access to such fraternity customs as rush in which attractive newcomers get invited to the house for inspection under party conditions and then are given a 'bid' if enough members agree they possess the 'right stuff' for membership.

Sometimes, the bid results in a good fit, and sometimes it results in conflict when an independent thinker among the new class of pledges raises concerns about the illicit or even illegal behaviors that the newcomers must brush away. The desired outcome of hazing is to achieve 100% pledge class unity – that class fully and wholly subservient to the wishes of the veteran members. Ironically, to get the 'trust' of the pledges, the senior members may lie, deceive, and deny all responsibility, notes Arnold. What occurs during the stress and chaos of a pledgeship marked by hazing is what the ethnographer John van Maanen refers to as 'cultural learning' for a group.

In its barest form, the pledgeship involves full indoctrination of the new members and total obeisance on the part of pledges as a socialization practice. Members justify their poor treatment of pledges and forcing them to endure often-squalid living conditions for weeks under the justification that everything asked of the pledges serves some important bonding purpose, noted Arnold. The chapter he lived with even used such terms as 'responsible hazing' and 'responsible drinking' that were oxymoronic since from rush until initiation, the chapter's behavior was flagrantly irresponsible and reckless. In the end, the outward result of an entire chapter as a model of control is a hazing chapter that Arnold stresses (p. 92) in Nuwer's *The Hazing Reader* must live with 'denial, dishonesty, self-centeredness, confusion, and so on.' All this is done by a group that projects the 'illusion of control' (Nuwer, 2004: p. 93). And a hazing chapter strives to admit members who respect the status quo and work to maintain a homogenous chapter; nothing incurs the collective wrath of a hazing group's members more than a pledge, who refuses to cower, or who actually quits pledging and rejects that group. Arnold establishes that the group treats the unhappy quitter with disdain, anger, and even threats. Conversely, pledges – away from the security of family and home – that buy into the addictive chapter mentality then get rewarded by the senior members with a supply of alcohol, parties, and access to desirable women who tolerate or even support the practices of the addictive chapter. Arnold says addictive groups and members have a dualistic approach to perceiving the world. Everything is all right or all wrong, and pledges are told it is 'our way or the highway.' Whatever good philanthropic activities the chapter supports are, in part, an attempt to cover up the confused, addictive nature of the chapter, Arnold concludes, citing the theories on the pervasive and

persistent nature of addiction noted by *The Addictive Organization* authors Anne Wilson Schaef and Diane Fassel that the national organizations and Greek Affairs staffs at colleges can make a difference if "they can turn away from a model of control and continued participation in an unhealthy system and through their actions demonstrate a healthier way of being" (Nuwer, 2004).

Stephen Sweet uses a frame of symbolic interactionism to explain how some undergraduates attracted to hard-hazing groups will do whatever it takes to belong. Herbert Blumer's symbolic interactionist construct, cited with regard to fraternal groups by Sweet, declares that human beings react to events because the events have meaning for them based on the social interaction they have with one another and then interpret those events with some selectivity – perhaps even outright justification and rationalization for activities banned by society. Blumer's theory in particular fits when applied to fraternal group members whose concept of self is at the time of pledging being crucially shaped. Sweet notes that the fraternal rings, T-shirts, and paddles represent part of the identity pledges, are accepting as they enter a crucial stage of their lives. In turn, the social relationships with those who already wear the colors and paraphernalia of the group they aspire to join can be a powerful lure to those young people who see enduring hazing as a necessary price to pay to get into an organization that has value. Conversely, says Sweet, those who quit pledging rather than endure not only suffer guilt because their pledge brothers will be asked to carry an additional burden, but they also lose a tie and part of their identity by forgoing all connection to the chapter they already may have sacrificed much for during early hazing. The research by T.A. Leemon, who lived with a fraternity chapter for one entire pledging period to observe it, demonstrates that fraternity chapters very deliberately in the hazing process set out to manipulate and to alter each pledge's concept of a self.

Ricky L. Jones also examines hazing in his book *Black Haze: Violence, Sacrifice, and Manhood in Black Greek-Letter Fraternities* (2004). Jones postulates that veteran fraternity members in hazing chapters love their pledges even if they put them through beatings with canes, fists, and paddles. While not every African-American Greek chapter hazes, the heaviest hazing chapters, according to Jones, demand the ability for pledges to withstand such sacrifices to demonstrate their readiness and willingness to maintain the group. Significantly, physical hazing at the chapter level is fundamentally the exact opposite of the relatively tame requirements for initiation that the national organizations put out in pledging manuals. Jones persuasively argues that hazing deaths in Asian fraternities at the University of Texas and University of California, Irvine, for example, demonstrate a requirement to endure physical challenges and a demonstration of sacrifice on the part of initiates. While the physical hazing may be a part of the black membership process in groups that violate their national organization's mandate to be hazing-free, it is also very much present in the rites of even some integrated chapters or all-Caucasian chapters that have seen new members hospitalized with physical injuries. Jones, himself a member of a black fraternity, has become a nationally known antihazing activist, particularly outspoken in his objections to hazing of a severe physical nature.

Psychologist Susan Lipkins, in her book *Preventing Hazing: How Parents, Teachers, and Coaches Can Stop the Violence, Harassment, and Humiliation* (2006), maintains that even short-term hazing can lead to long-term, even lifelong, psychological, and physical consequences for hazing victims. Short of death, psychological trauma due to hazing may be an even more pernicious problem than physical injuries for the latter nearly always heal, while victims report an inability to get on with their lives in normal fashion due to the afflictions of hazing, according to Lipkins.

Hazing in U.S. Universities

Hazing in fraternities and sororities in the United States involves expectations of senior members that potential new members – often called pledges or associate members – will perform stunts that demean, degrade, or endanger them. Those that endure the group's humiliation prove their willingness to conform to a perceived status quo. The members who insist newcomers endure such barbaric initiations claim they are merely protecting established tradition and ensuring group solidarity. They maintain that hazing weeds out potential members who lack the wherewithal to do anything the fraternal chapter asks of those who seek membership. It also establishes a senior pecking order in which new members learn the rules of precedence and a need to respect both senior members and alumni as well.

Thus, hazing is common, albeit forbidden, among fraternities and sororities whose reason for being at educational institutions is to instill a lifelong commitment to leadership, community service, and the worth of lifelong friendships and mentoring. This general 'mission' coincides with functionalist theories of rites of passage extending back to Arnold van Gennep (*Les rites de passage* (*The Rites of Passage*), 1909).

Hazing in university and college fraternities and sororities is an illicit rite of passage (against the rules of the institution) that provides opportunities for veteran members to include or exclude new members on the basis of a variety of trials that involve varying degrees of physical and psychological stress. In all too many cases, the theory of social exchange put forth by psychologists Harold H. Kelley and John W. Thibaut in *The Social Psychology of Groups* (Tiger, 1969) describes the recurring reality. According to this theory, newcomers submit to whatever torture or trials are asked of them, comforted by the assurance that all abuse will cease after the organization declares them full members. During the next cycle, the new veterans get to turn the tables and haze the next set of newcomers.

All new pledge classes experience much the same brutal hazing their predecessors endured. Hazing can increase in intensity if members are inebriated or inclined toward sadism (Nuwer, 1990). After initiation, the hazed become the hazers and return the ordeals they experienced in equal or greater intensity and measure to the next pledge class (Nuwer, 1990, 1999a).

Deaths of pledges in Greek organizations have occurred under bizarre circumstances as the database of hazing deaths kept by Nuwer in *Wrongs of Passage* and online (http://www.hanknuwer.com/hazingdeaths.html) attests. Some have consumed lethal amounts of alcohol, being required by members to fill garbage pails with the collective vomit of new members. Some have perished after being dropped off far from campus (with victims dying in falls, auto accidents, and by drowning). Some have endured hours of strenuous exercise in steam rooms with fatal results. Some have died after being on the receiving end of beatings with a paddle, fists, or cane, according to Nuwer's list of hazing deaths.

History of University Hazing in the United States

In his 1990 book *Broken Pledges: The Deadly Rite of Hazing*, Nuwer demonstrates that the rampant hazing in European medieval universities such as the fifteenth-century practice of pennalism developed over the next 200 years into sometimes savage hazing practices quite similar to the aptly named Hell Nights of today's hazing fraternities and sororities. In France and Germany, the hazed pledges wore a cap similar to the beanies worn by pledges until all national groups began outlawing them as symbols of hazing around 1979, according to Nuwer's *Broken Pledges: The Deadly Rite of Hazing*. At Cambridge and Oxford in England, physical beatings and enforced servitude among even the aristocracy was carried out in a custom known as fagging where new boys on campus became the manservants of older students.

Hazing deaths were not always attributed mainly to fraternities historically. Rather, they were a greater problem in the so-called 'class hazing' that pitted first-year students against upperclassmen. (While female class hazing existed, not once did a death occur to either a first- or second-year female, but a female cook did perish in 1894 when an undergraduate piped chlorine gas into a class party to disrupt it.) Eighteen of the 25 hazing deaths of males that occurred on U.S. college campuses from 1838 through 1927 were a result of freshman-sophomore class hazing excesses during battle royals, pranks, and organized fights to capture class flags, but not because of fraternity hazing, which claimed the lives of seven young men, according to Nuwer's *Broken Pledges* appendix of deaths. During the late 1920s, thanks to more awareness on campus and an outpouring of condemnation of hazing by students themselves, hazing of first-year students no longer included battles for class flags and class pennants that had seen so much violence. From 1928 through March 2014, only two first-year hazing deaths (Cheyney State and the University of Richmond) occurred, the rest entirely committed by hazers in fraternities, sororities, athletic teams, and one band (Florida A & M), according to Nuwer's list of hazing deaths and his appendix in *Wrongs of Passage*.

Fraternities and sororities often trace their origins back to literary and honor societies that flourished back in 1776. The first fraternity per se was the Kappa Alpha Society founded in 1825 at Union College in New York State. The first fraternities and sororities emulated early literary societies in their educational values, and their founders were students themselves who wanted to engage in intellectual debate as well as to socialize. In addition to establishing the solemn initiation rituals that often borrowed symbolism from Masonic initiations, the early fraternity chapters also hazed new members on occasion in usually ordeals known as stunts. Some stunts included riding a real or mechanical goat or tossing a newcomer in the air on a blanket. Injuries occasionally occurred as a result of youths getting carried away. Nuwer's *Broken Pledges* documents injuries to two University of Georgia Zeta Chi pledges that jumped out a window when an older member whipped out a pistol as a prank.

The first U.S. fraternity death was Kappa Sigma Society member Mortimer Leggett in 1873 at Cornell University. At least one newcomer has perished while enduring hazing every year from 1970 to 2013, according to Nuwer's *Wrongs of Passage* and the Internet list of verifiable hazing deaths. The last one was an alcohol-related death at Baruch College in New York State in December 2013 (http://www.hanknuwer.com/hazingdeaths.html), one of five hazing deaths in 2013.

Thus, some years far more deaths than a single death have occurred in Greek organizations. In 2012, five deaths of fraternity men in U.S. colleges occurred by hazing that stemmed from alcohol overdoses; a sixth death occurred by drowning: a male pledge was asked to swim in a reservoir at the University of Idaho (http://hanknuwer.com/hazingdeaths.html). Because some law enforcement officers lack a clear understanding of what hazing actually is, it is plausible that the number of hazing deaths on the Nuwer's list is lower than might actually be the higher total. Similarly, neither universities nor Greek national organizations are eager to claim a death as related to hazing lest that admission result in damages during civil litigation.

Hazing deaths are not limited to on campus to fraternities and sororities, but those two groups have experienced the majority of incidents. In the United States, the vast majority of the 180 hazing deaths from 1838 to 2013 have involved newcomers in fraternities and, to a lesser extent, in sororities. Far more males than females have perished in Greek organizations because of hazing, and experts uniformly agree that fraternity hazing deaths have proven far more common than sorority hazing deaths. According to a University of Maine national survey, about half of all students acknowledge that they belong to groups that haze. Thus, while hazing in sororities is often reported, it only occasionally rises to the level of an actual crime and is more likely to be addressed by the hazers' institution than by a criminal prosecution. It is important to note that deaths in local, unrecognized, or suspended fraternities have resulted in deaths at several institutions, including the University of Nevada, SUNY Plattsburgh, Chico State, and SUNY Geneseo.

Deaths by hazing also have been reported in countries such as the Philippines, India, Japan, Canada, and Great Britain (Nuwer, 2004).

Hazing and Alcohol Abuse

Alcohol was consumed by some fraternal chapters in the nineteenth century through 1939, but such factors as alumni, faculty, and administration supervision of chapters resulted in far less tolerance for drunkenness or using alcohol as a sort of litmus test of new member readiness during hazing. Significantly, fraternities likely did not experience a single reported

hazing death due to alcohol until 1940. That year, Hubert L. Spake, Jr. died following a mandatory drinking session at the University of Missouri while pledging Theta Nu Epsilon, according to Nuwer (1990). Clearly, with the escalating number of hazing deaths from 1970 to December 2013, according to Nuwer's list of deaths, a case can be made that the presence of alcohol has made hazing rituals far more extreme and life threatening than they were prior to 1969.

Research published in Nuwer's online list of hazing deaths demonstrates that the majority of hazing deaths in Greek groups from 1970 to 2013 involve an overdose of alcohol. In the period 2012–13, six of the last eight fraternity hazing deaths involved alcohol. Other victims from 1873 to 2012 have died from beatings, car wrecks, pedestrian accidents, falls from buildings or high elevations, burns, drowning, choking, ingestion of many gallons of water or other liquids, and other causes. A small number of suicides have occurred immediately following hazing activities and are listed on Nuwer's list of hazing deaths.

Here are three examples of hazing deaths due to alcohol from the Internet 'List of Hazing Deaths' maintained by Hank Nuwer.

- In 1980, University of South Carolina Sigma Nu pledge Barry Ballou choked to death after passing out at a ritualized drinking session attended by an alumnus and members.
- Pi Kappa Alpha pledge David Bogenberger, a Northern Illinois University freshman, died in 2012 after being asked to chug copious amounts of hard alcohol. Police charged 22 individuals with crimes, including five felony counts.
- In 2012, Fresno State University Theta Chi pledge Philip Dhanens, a 350-pound former football player, died following a weekend binge. He died at a hospital where he had been taken for assistance.

U.S. Laws against Hazing

Hazing may be illicit – against the rules of a collegiate institution – or forbidden by state law. As of 2012, hazing was illegal by statute in 44 states, but as of March 2014, there is no federal law regulating hazing; although, activists such as Lianne Kowiak, mother of a Theta Chi pledge killed at Lenoir Rhyne University, advocates for such a law, according to Bloomberg.com (24 July 2013). In most states, hazing is most commonly a misdemeanor offense. Florida has the strictest possible penalty among all U.S. states, allowing a sentence of 5 years to be imposed upon conviction for felony hazing. Nonetheless, the courts have traditionally imposed light jail sentences, often requiring merely community service or fining individual hazers and/or their chapters. Hazing can be hard to establish since these illegal actions often take place behind closed doors. In addition, after a death or serious incident, uncooperative members refuse to share details of what took place when investigators interview them. This is why prosecutors for the state often file more easily proven charges such as assault or serving alcohol to a minor because hazing is a more difficult crime to prove in court. Felony convictions for repeated hazing beatings were imposed on a Florida A & M fraternity, and a Chico State fraternity member was convicted of a felony following the death of a pledge required to drink so much water than his body chemistry was altered.

University Hazing Practices and Deaths

The increasing numbers of prospective members injured or killed by hazing reveals that they stand ready to do whatever is necessary for acceptance into an organization. When a fraternity or sorority pledge fails to complete the pledge process, it can be a traumatic experience for individuals who fail to cross the liminal space, particularly if they feel less than full-fledged adults and must ask either their parents or school officials to intervene on their behalf.

Sororities have been connected to eight deaths of females and one death of a male in alleged hazing incidents, according to Nuwer's list of hazing deaths. In 1970, an Eastern Illinois sorority member became the first to die after she perished from effects of a head injury incurred in a vehicular accident after she had resisted being 'kidnapped' by pledges that intended to abandon her in the country as a prank, according to Nuwer's *Wrongs of Passage*. Three female deaths have been attributed to drowning in dangerous ceremonial initiations, one at Virginia State and two at California State, Los Angeles, according to Nuwer's list.

A 2012 lawsuit by the mother of a deceased sorority pledge at East Carolina University maintained that the 2010 deaths of her daughter and a second pledge were directly caused by sleep deprivation due to hazing. According to that lawsuit, East Carolina State University Delta Sigma Theta pledges Victoria Carter, 20, and Briana Latrice Gather, 20, died in a car accident. In addition to the aforementioned two sorority deaths at Eastern Carolina University, one additional death occurred at Plymouth State University during an automobile accident while pledges allegedly were made to lie flat on the floor of an SUV that then overturned. None of these deaths involved alcohol. However, in 2008, a total of 12 Chi Omega sorority and Sigma Nu fraternity members at Utah State University were charged with crimes following the alcohol-related hazing of Michael Starks, 18, conducted by both chapters, according to Nuwer's list. In addition, in March 2014, an alleged hazing incident involving Kappa Kappa Gamma sorority and Sigma Alpha Epsilon (SAE) fraternity at the University of Connecticut resulted in the hospitalization of a sorority member admitted with a life-threatening blood-alcohol account, according to widely published media accounts and an email from the victim to Hank Nuwer sent on 12 March 2014.

In addition to pledge deaths, the so-called pledge 'sneaks' routinely occur in which pledges haze senior members to retaliate for what they themselves have gone through and endured, and these have resulted in deaths at schools such as Eastern Illinois University, the University of Texas, University of Georgia, and Frostburg State University, according to the appendix listed in Nuwer's *Wrongs of Passage* (1999b). Such a practice is often encouraged by the membership as a means of forging pledge solidarity, according to the same source. The latest example of the reverse hazing of members by pledges has been the death of SAE member George Desdunes who was 'encouraged' by pledges to drink what proved to be a deadly amount of alcohol in a question-and-answer session at his

Cornell University chapter house in 2011, according to *The New York Times* of 12 April 2012.

As mentioned, hazing can also have serious consequences even without a death. Many male and female students have been hospitalized for acute alcohol intoxication, for example. Greek chapters have been punished for such behaviors as activities of a sexual nature, physical pummeling, verbal abuse, overwork, sleep deprivation, branding with chemicals, and a host of bizarre pranks intended to amuse veteran members, according to the list of examples published in the appendices of Nuwer's *Broken Pledges* and *Wrongs of Passage*.

To be sure, hazing can also involve activities that do not qualify as deadly or particularly demeaning such as requiring a pledge to sing a song or carry a veteran's book. Nonetheless all national and international fraternal organizations ban these activities as well since the possibility exists that a rogue member or members might get creative with a relatively noninjurious act of hazing and take the activity to a potentially harmful level. In addition, what may seem like innocuous hazing to a perpetrator may be perceived as threatening to a newcomer. Fraternal leaders such as Associate Dean of Students Travis Apgar of Cornell University (http://www.hazingprevention.org/hazing-information/hidden-harm-of-hazing.html) refer to resultant psychological trauma as a type of 'hidden harm.' Even the most stable of new recruits can break down when subjected to night after night of verbal abuse, subjugation, and sleep deprivation, particularly when forced to sleep on a floor in confined quarters and to leap up on the instant to carry out some inane errand that a veteran member has conjured up. Nuwer, in the *Chronicle of Higher Education* (26 November 1999a), termed these latter examples as examples of cultlike systematic hazing.

Prosecuting and Preventing Hazing

From the first fraternity hazing death in 1873 to deaths in 1973, there appear to have been few arrests and no convictions for fraternity and sorority hazing deaths, according to Nuwer's *Broken Pledges* (1990: pp. 286–298). And while the adviser in the 1974 shooting death for a hazing at Bluefield State was convicted and served time for killing a Tau Kappa Epsilon pledge, and a North Carolina A & T University in 1987 received a 2-year sentence for pledge beatings, it was not until 1999 that tightened state laws and increasing media attention led to stricter enforcement and a small number of arrests resulting in convictions. Most notable was the 2007 sentencing of nearly 2 years in prison for two Florida A & M fraternity men who pleaded no contest to felony charges of beating a Kappa Alpha Psi pledge; they served jail time but on appeal had the charges expunged from their records.

By 2010, more arrests and a handful of convictions for serious hazing cases began to get the attention of the press. For example, two young men were convicted of misdemeanor hazing in the 2008 death of SAE pledge Carson Starkey and received jail sentences of 30 days each, according to widely published media accounts such as CBS Sunday Morning (5 February 2012). On the other hand, in the 2010 death of a Radford University fraternity pledge, the court punishment was merely $1000 each and no jail time for five Tau Kappa Epsilon members in a plea deal, according to the *Orlando Sentinel* (11 July 2012).

Perhaps more effective than laws curtailing hazing have been attempts by international organization such as SAE to ban or shorten the pledge period. In March 2014, according to the Web site of the parent SAE organization, all pledging now has ceased due to the deaths of 10 SAE pledges, the most of any national fraternity according to Bloomberg News (8 March 2014) and Nuwer's Internet list of hazing deaths (15 March 2014).

Another effective best practice was the dry house movement followed most conspicuously by all chapters of the large national fraternity Phi Delta Theta that in 2000 removed alcohol from the premises of chapter houses, thereby eliminating the substance that has caused the most hazing deaths after 1970, according to Nuwer (2001). On 14 March 2014, executive Vice President of Phi Delta Theta, Bob Biggs told the *Washington Post* that in addition to a dramatic decrease in hazing claims, undergraduate membership increased by 25%.

Hazing Judgments by the Courts

Civil lawsuits in the aftermath of an injury or death blamed on hazing have become quite common. The parents of Chad Meredith, a University of Miami pledge who drowned when forced to swim across a lake by older Kappa Sigma members, resulted in a $14 million judgment against those young men. The highest settlement ever paid by a university was $6 million in 2002 by Massachusetts Institute of Technology to the parents of Scott Krueger who died of alcohol intoxication following a Phi Gamma Delta pledge party.

Prevention of Hazing

As might be expected, since deaths by hazing largely occur in fraternities and to a lesser extent in sororities, the main anti-hazing activists are undergraduate members, alumni, and national officers of fraternities and sororities. The two most influential organizations are the Web-based Stophazing.org created by University of Maine hazing researcher Elizabeth Allan and the national group HazingPrevention.Org (HPO).

Stophazing's Allan is a professor at the University of Maine in Higher Education Leadership, one of the few academic programs offering a hazing studies concentration. She and her Maine colleague Mary Madden completed in 2011 a 3-year research project on hazing with responses from 11 482 college students enrolled in 54 colleges. The survey response rate was 12%.

Slightly more than half of all respondents acknowledged participating in acts of hazing as members of student groups such as fraternities and sororities. In her essay for *The Hazing Reader* titled 'Hazing and Gender: Analyzing the Obvious,' Allan notes that empirical research on gender differences is scant, but while a national survey distributed to Greek professionals found that 44% had to deal with reported hazing cases, the number of violent and otherwise physical hazings were far fewer than those committed by male students.

HPO is an activist organization dedicated to empower people to prevent hazing in college and university student groups. HPO's board of directors and numerous volunteers and small staff provide antihazing education through conferences, Webinars, and training sessions. HPO sponsors its annual

Hank Nuwer Anti-Hazing Hero Award, which to date has honored mainly fraternity and sorority undergraduates who effected positive changes in their own chapters to curb hazing practices. The award was named for the author of this article to commemorate his research on hazing that has resulted in four scholarly books on the topic through 2012 (*Broken Pledges: The Deadly Rite of Hazing, High School Hazing, Wrongs of Passage, The Hazing Reader*). In January 2014, Nuwer published *Sons of the Dawn: A Basque Odyssey*, a novel that Kirkus Reviews praised online (10 January 2014) for its treatment of hazing and bullying in the Old West.

In addition to these two antihazing groups, there is a college archive that attempts to put all hazing scholarship under a single collection. Buffalo State College's (BSC) Butler Library has since 2006 sponsored an extensive Hazing Collection available without charge to hazing researchers and undergraduate students alike (http://bsclib01.buffalostate.edu/library/archives/). Under the direction of archivist Daniel Di Landro and BSC Vice President Maryruth Glogowski, the Hazing Collection in Buffalo, New York, has endeavored to house every hazing-related scholarly article, doctoral dissertation, master's thesis, book, and miscellaneous research items for free use by researchers. Before the collection was established, one difficulty that researchers face was that the relatively small literature related to hazing scattered at widely separated libraries and institutions, making research an expensive, time-consuming challenge for researchers, according to author John Nicoletti in *Violence Goes to College* (2009: p. 200).

While a number of best practices to curtail hazing have been championed by a number of educators, no single solution has been found to stamp out hazing. Nuwer, in *Broken Pledges* (1990), along with other authors, has argued that bystander intervention might have prevented specific hazing incidents from leading to serious injuries and deaths in a number of fraternity tragedies. Bystander intervention refers to the practice of emboldening those who witness crimes or potential criminal behavior to step in and take action to halt the behavior before it escalates, according to *The New York Times* of 9 February 2014. The writings and seminars by hazing intervention expert Alan Berkowitz very specifically target bystander intervention as an important means of intervention before a hazing activity gets to the point of no return. In addition, a great many U.S. educational institutions use social norms data in an attempt to discourage binge drinking and hazing by stressing to undergraduates that such unacceptable practices are anything but normal in an attempt to sway behavior changes through marketing campaigns such as posters in college classroom buildings and residence halls.

Many other education experts, including Christopher Bollinger, coauthor of *Violence Goes to College*, have argued for the value of substituting useful, benign group-building activities in place of hazing practices. HPO seminar leader Kim Novak offers Greek life professionals hands-on suggestions for activities such as ropes courses that encourage group unity to achieve a common goal.

In 2013, the VIV Family Outreach Foundation, founded by the surviving families of a 2007 Virginia Tech (Virginia Polytechnic Institute and State University) school shooting massacre, brought together nine experts (including in hazing prevention) to create a new project termed the 32 National Campus Safety Initiative that has identified best practices for institutions to employ that counter violent campus behaviors such as hazing and sexual assault. A pilot program was initiated with a number of institutions to provide a voluntary rating system so that an individual institution not only can judge how it measures up in terms of combating hazing and other behavioral maladies, but also take steps to shore up areas where deficiencies appear to occur.

As the number of deaths associated with hazing continues to climb, a trend of late has been the zero tolerance toward the practice practiced by a number of institutions. In addition to the expulsion of chapters caught hazing, a number of universities also have created hazing task forces composed of faculty, staff and, in some cases, outside experts.

For example, following the hazing death of George Desdunes, 19, Cornell University President David Skorton not only wrote a widely quoted Op-Ed article for *The New York Times* (23 August 2011) titled 'A Pledge to End Fraternity Hazing,' but his Greek Affairs staff at the venerable New York institution issued a clear warning to fraternal groups that the new hazing policy was zero tolerance. The no-nonsense new policy resulted in nine fraternities cited and/or punished by Cornell for hazing from 2012 to March 2014, according to that institution's Web site. In addition, Cornell established the Recruitment-Acceptance-Retention-Education Task Force with one of its main agenda items being to find and to research best practices for curtailing hazing in fraternities and other student groups.

In California, following the alcohol-related birthday death of a Chico State University pledge, which its President Paul Zingg termed hazing-related, all campus fraternities and sororities were suspended in November 2012. The unprecedented step was taken because of a rash of nonhazing-related deaths of late, as well as the fact that this was at least the fourth hazing death at Chico State. Likewise, Central Florida University, which had a near fatality during pledging for Kappa Alpha Psi, put an end to all pledging and fraternal social activities in 2013, concerned by reports that pledging activities had in some cases escalated into hazing. The University of Virginia ordered all pledging to cease immediately in 2013 or the offending chapters would be shut down. The University also started the antihazing activist group called Hoos Against Hazing (http://www.virginia.edu/hazing/).

If these hard-line steps fail to work, no doubt a small number of universities will follow the example of Alfred University. In 2002, following a number of hazing deaths in local and national fraternities, the Alfred Board of Trustees decided regulation of Greek groups was not working. Consequently, the Board moved to shut down all Greek houses permanently. However, even though media outlets such as the Bloomberg News (Editorial, 7 January 2014) clamor for colleges to shut down permanently all fraternal systems, Alfred was the last to end a long-standing Greek system, and it unlikely many more colleges will risk alumni outrage by banning fraternities and sororities. National fraternities and sororities vociferously defend the right of public universities to maintain a freedom of association, making it unlikely that any educational institutions (besides the occasional private college) will ever ban an entire Greek system. At present, besides Alfred, the handful of private colleges in the historic past to close their Greek systems

Box 1 Chronology of fraternity and sorority hazing in the United States

1873 Cornell first-year student Mortimer N. Leggett died in a fall into a gorge while members were taking him on a traditional walk in the country.

1928 National Interfraternity Conference leaders voted to end all hazing.

1940 The first alcohol-related fraternity hazing death occurred in the United States. It was at the University of Missouri.

1970 A female Eastern Illinois sorority member died in a vehicle accident as pledges tried to abandon her in the country. There would be a death every year after (and some years many deaths) in Greek life until 2013.

1978 A death of a pledge named Chuck Stenzel at Alfred University marked the beginning of the antihazing movement in the United States led by Eileen Stevens, a New York housewife and the pledge's mother. She called her organization CHUCK, the Committee to Halt Useless College Killings.

1978 The movie Animal House was released, mocking the practice of fraternity hazing.

1994 The beating death of Michael Davis for a Southeast Missouri State black fraternity chapter created outrage over physical hazing. He died in the back seat of a member's car after being beaten by members who had abducted him from the library.

2000 As deaths mount, the National Interfraternity Conference and National Panhellenic Conference plan measures to control hazing and binge drinking. Phi Delta Theta officially ordered its chapter houses to become alcohol-free in an attempt to end hazing and binge drinking deaths.

2002 Hank Nuwer, the author of *Wrongs of Passage*, issues a challenge to fraternity and sorority leaders to begin a hazing task force to address the issue nationally. Subsequently, a fraternity antihazing activist named Dan Bureau takes the challenge and convenes the first-ever task force on hazing.

2013 A hazing death in December at Baruch College in New York extended the unbroken stretch of hazing deaths 43 years from 1970 to 2013.

2014 Following the deaths of 10 pledges, the largest national fraternity in the world, Sigma Alpha Epsilon, bans all pledging.

included Middlebury College (1990) (1990: p. 147), Williams College (1962) (1990: p. 242), and Colby College (1983) (1990: p. 242). A few private colleges such as Bates College in Maine never have permitted fraternities. The last public university to ban pledging for a semester was the University of Alabama in November 2012, according to *Fraternal Law Newsletter* (**Box 1**).

Healing Practices: Alternative and Complementary

Abstract

This article describes the rise in complementary and alternative medicine (CAM). It also looks at the typical user. It describes the range of treatments available and how they differ from orthodox medicine (OM). This article considers some of the controversies in this area specifically which (and why) people choose CAM over OM. Secondly, it looks at the evidence for the efficacy of CAM.

The Rise of Complementary and Alternative Medicine and Healing Practices

Complementary and alternative medicine (CAM) has gained wide recognition and CAM is now big business (Ernst and Furnham, 2000). CAM seems also to be favorably perceived by many general practitioners (GPs) (Easthope et al., 2000). The rise of CAM has led to a UK House of Lords inquiry into six aspects of CAM: evidence, information, research, training, regulation and risk, and British National Health Service (NHS) provision (Ernst, 2000).

The figures of before the millennium showed the beginning of this rise. In 1993, 34% of all Americans visited a CAM therapist, more than visits to all US primary care physicians put together. Expenditure was estimated at $13.7 billion per annum. By 1998, 47% of all Americans were estimated to visit a CAM practitioner. Annual visits rose from 427 million in 1990 to 629 million in 1997 (Eisenberg et al., 1998).

Individuals spend £1.6 million per annum on CAM therapies, the NHS about £40, and £500 million is spent on products (White and Ernst, 2000). Some estimates suggested that this number has doubled but it is difficult to get reliable statistics.

There are many reports of how much people spent (Nahin et al., 2009).

A 2012 *Journal of the American Medical Association* report noted that in 2012, £130 million was spent on CAM research (Offit, 2012).

All this attests to the increasing popularity of CAM and presumably the belief by the general public that they are getting value for money, in the sense that it 'works for them.'

Controversy

Since the turn of the twenty-first century, there has been unprecedented and sour debate as to the efficacy of alternative medicine (Vincent and Furnham, 2001). Complementary medicine has been a wildly controversial topic over recent years, as techniques have been rigorously scientifically tested and various fraudsters revealed. Singh and Ernst (2008) in the book *Trick or Treatment* evaluated 40 complementary techniques and were scathing in their findings. They found that scientific evidence for the efficacy of these methods was lacking, and that the methods were not just ineffective, but positively dangerous in some cases. For example, methods such as homeopathy are labeled merely as placebos lacking in credible, repeatable effects. Singh was later sued by the British Chiropractic Association for libel for comments associated to the book, although they later dropped the case. Other widely available books such as *Suckers: How Alternative Medicine Makes Fools of Us All* by Shapiro (2008) follow a similar line.

However, many CAM practitioners are wary of, and hostile to, the scientific testing of their claims (Leach and Gillham, 2011). An Australian study found that, although 92% of practitioners believed evidence-based, scientific practice was useful, only a small amount actually practiced it in the correct manner. Their suggestion is that, to push through this inertia, training of clinicians is necessary to reinforce how evidence-based practice is useful and works. Stoneman et al. (2013), however, see the problem being in the public consciousness and support of alternative medicines and therapies, saying that this is the most difficult thing to change.

Critics have lampooned CAM. A good example is that of Prof. David Colquhoun (http://www.dcscience.net/, http://www.ucl.ac.uk/npp/research/dc) who has a Web site dedicated to CAM quackery and fraud. In one entry, he gives the following funny and cynical definitions:

- Homeopathy: giving patients medicines that contain no medicine whatsoever.
- Herbal medicine: giving patients an unknown dose of an ill-defined drug, of unknown effectiveness and unknown safety.
- Acupuncture: a rather theatrical placebo, with no real therapeutic benefit in most if not all cases.
- Chiropractic: an invention of a nineteenth-century salesman, based on nonsensical principles, and shown to be no more effective than other manipulative therapies, but less safe.
- Reflexology: plain old foot massage, overlaid with utter nonsense about nonexistent connections between your feet and your thyroid gland.
- Nutritional therapy: self-styled 'nutritionists' making untrue claims about diet in order to sell you unnecessary supplements.
- Spiritual healing: tea and sympathy, accompanied by arm-waving.
- Reiki: ditto.
- Angelic Reiki: The same but with added "Angels, Ascended Masters and Galactic Healers." Excellent for advanced fantasists.

 http://dx.doi.org/10.1016/B978-0-08-097086-8.14004-8

- Colonic irrigation: a rectal obsession that fails to rid you of toxins that you did not have in the first place.
- Anthroposophical medicine: followers of the mystic barmpot, Rudolf Steiner, for whom nothing whatsoever seems to strain credulity.
- Alternative diagnosis: kinesiology, iridology, vega test, etc., various forms of fraud, designed to sell you cures that do not work for problems you have not got.
- Any alternative 'therapist' who claims to cure acquired immunodeficiency syndrome or malaria: agent of culpable homicide.
- Libel: A very expensive remedy, to be used only when you have no evidence. Appeals to alternative practitioners because truth is irrelevant.

What Are Complementary and Alternative Medicines?

The great range of CAM inevitably means there is a considerable diversity of therapies and their attendant theories and philosophies. Yet there are common themes in the philosophies of CAM. Aakster (1986) believes that they differ from orthodox medicine (OM) in five ways:

1. Health: Conventional medicine sees health as an absence of disease, whereas alternative medicine frequently mentions a balance of opposing forces (both external and internal).
2. Disease: Conventional medical professionals see disease as a specific, locally defined deviation in organ or tissue structure. CAM practitioners stress body-wide signs, such as body language indicating disruptive forces and/or restorative processes.
3. Diagnosis: Regular medicine stresses morphological classification based on location and etiology, while alternative interpretations often consider problems of functionality to be diagnostically useful.
4. Therapy: Conventional medicine often claims to destroy, demolish, or suppress the sickening forces, while alternative therapies often aim to strengthen the vitalizing, health-promoting forces. CAM therapists seem particularly hostile to chemical therapies and surgery.
5. The Patient: In much conventional medicine, the patient is the passive recipient of external solutions, while in CAM, the patient is an active participant in regaining health.

Aakster described three main models of medical thinking: The pharmaceutical model is a demonstrable deviation of function or structure than can be diagnosed by careful observation. The causes of disease are mainly germlike and the application of therapeutic technology is all-important. The integrational model resulted from technicians attempting to reintegrate the body. This approach is not afraid of allowing for psychological and social causes to be specified in the etiology of illness. The third model has been labeled holistic and does not distinguish between soma, psyche, and social. It stresses total therapy and holds up the idea of a natural way of living.

Furnham (2000) used factor analysis to see how over 500 members of the general British public classified 39 different types of CAM on whether they had heard of it, know how it worked, whether they had tried it, and whether they believed it worked. A pattern emerged with art therapies (e.g., music, dance), talk therapies (i.e., counseling), and 'foreign techniques' (e.g., Reiki, Shiatsu). The 'big six' most established therapies (acupuncture, chiropractic, homeopathy, medical herbalism, naturopathy, and osteopathy) were often grouped together, presumably because they are seen as most established and regulated, despite the fact that they are based on very different methods and philosophies. In essence, he showed that some CAM are very well known and trusted while others are very little known.

Gray (1998) argued there are currently four quite different perspectives on CAM:

1. The biomedical perspective: This is concerned with curing of disease and control of symptoms where the physician-scientist is a technician applying high-level skills to the patient. This perspective asserts (1) that the natural order is autonomous from human consciousness, culture, morality, psychology, and the supernatural; (2) that truth or reality resides in the accurate explanation of material (as opposed to spiritual, psychological, or political) reality; (3) that the individual is the social unit of primary importance (as opposed to society); and (4) that a dualistic framework (e.g., mind/body) is most appropriate for describing reality. This approach is antagonistic toward and skeptical of CAM, believing many claims to be fraudulent and many practitioners unscrupulous.
2. The complementary perspective: Though extremely varied, those with this perspective do share certain fundamental assumptions: (1) believing in the importance of domains other than 'the physical' for understanding health, (2) viewing diseases as symptomatic of underlying systematic problems, (3) a reliance on clinical experience to guide practice, and (4) a cogent critique of the limits of the biomedical approach. Interventions at the psychological, social, and spiritual level are all thought to be relevant and important, supporting the idea of a biopsychosocial model. Many advocates are critical of biomedicine's harsh and often unsuccessful treatments, and point out the paradox of biomedicine often not being based on 'solid scientific evidence.'
3. The progressive perspective: Proponents of this perspective are prepared to support either of the above, depending entirely on the scientific evidence. They are hardened empiricists who believe it is possible to integrate the best of biomedicine and unconventional approaches. Like all other health care professionals, their approach is not value-free – the advocates of this approach welcome the scientific testing of all sorts of unconventional therapies.
4. The postmodern perspective: This approach enjoys challenging those with absolute faith in science, reason, and technology, and deconstructing traditional ideas of progress. Followers are distrustful of, and cynical toward, science, medicine, the legal system and institutionalized religion, and even parliamentary democracy. Postmodernists see truth as a socially and politically constructed idea and believe orthodox practitioners to be totalitarian persecutors of unconventional medicine. Proponents of this position argue that (1) to have a complementary perspective in any debate is healthy, (2) CAM practitioners are also connected to particular economic and theoretical interests,

(3) a variety of values and criteria for assessing success is beneficial, and (4) the ill people themselves should be the final arbiters of the success of the therapy.

There is more diversity than unity within CAM. While there have been calls to find regulatory bodies to oversee all CAM practices, this has proved very difficult because of the theoretical, historical, and political differences between the various CAM specialties.

Research in CAM

The popular interest in CAM has been matched by a relatively sudden and dramatic increase in research into the two central questions in this area:

1. Does it work?
   Is there good evidence from double-blind, placebo-controlled, randomized studies that the therapy 'cures illness' as it says it does? That is, is there any indisputable scientific evidence that documented findings of success are due to anything more than a placebo effect? Properly designed and executed studies are complex, very expensive, and similar to the research effort to determine the efficacy of psychotherapy. Indeed, it is the extensive research into the placebo effect that makes psychological input particularly valuable (Vincent and Furnham, 2001). The answer to the question is that either very little or no good evidence (from the gold-standard randomized, controlled, double-blind studies) is available for the efficacy of most CAM, with the possible exception of herbalism. However, as more and more sophisticated meta-analyses are published, there does seem to be clear evidence for small but robust positive effects of specific CAM treatments (Ernst and Pittler, 1998).
2. Why choose it?
   If the evidence is limited, equivocal, and indeed often points to lack of efficacy, the central question must be why do patients choose at their own expense to visit a CAM practitioner? What do they get from the treatment? Why do they persist? This is where there have been many psychological studies (Furnham, 2002; Vincent and Furnham, 2001). They concern the often mixed motives that patients have in shopping for health treatments.

   The principal reason for individuals beginning any CAM treatment appears to be that they regard it as more natural and effective, and it allows a more active role for them. The second reason is the failure of OM to provide relief for specific (usually chronic) complaints. The adverse effects of OM, and a more positive patient–practitioner relationship, are also important for many patients. There is little to support the widely held view that CAM-seeking patients are especially gullible or naïve, or have unusual (neurotic) personalities or (bizarre) value or belief systems. However, comparisons of users and nonusers of CAM have shown evidence of different beliefs about health and disease in general. To some extent, CAM patients are as much 'pushed away' from OM, which does not deliver what it promises as 'pulled toward' CAM by its promises and different treatments.

CAM and the Medical Profession

There have been a limited number of studies of practicing doctors' (usually general practitioners') attitudes to CAM. In an early study, Wharton and Lewith (1986) found high level of interest in CAM among GPs. In total, 38% of the 145 respondents had received some training in CAM, and 15% wished to arrange training. In the previous year, 76% had referred patients for alternative treatment to a doctor, 72% had referred patients to nonmedically qualified practitioners, and 70% thought that the more acceptable techniques (e.g., hypnosis, acupuncture, spinal manipulation, and homoeopathy) should be available through the NHS. It should be noted that homoeopathic treatment has been available through the NHS from its inception.

Although early studies were relatively small scale, they yielded comparable results, showing a generally high level of interest in CAM among GPs. Critics have noted many quite orthodox techniques (e.g., manipulation, counseling) were wrongly classified as complementary, so exaggerating the interest in truly complementary techniques (Vincent and Furnham, 2001). GPs may also not be representative of the orthodox medical profession. Visser and Peters (1990) suggested that GPs have a more pragmatic attitude to medicine than their hospital colleagues, which makes them more willing to accept CAM, although they may remain skeptical of its efficacy (Furnham et al., 1995).

The consistent message from these studies is that most GPs seemed favorably disposed toward CAM therapies, particularly the better established therapies like acupuncture, chiropractic, and osteopathy, with homoeopathy being the most popular of the CAM therapies.

There is also a growing literature on the attitudes, beliefs, and expectations of medical students, as opposed to qualified practitioners, toward CAM (Easthope et al., 2000). Complementary medicine has even been introduced to the curriculum of some medical schools. Furnham et al. (1999) went on to examine preclinical medical students' attitudes specifically to the following five complementary therapies: herbalism, homoeopathy, hypnosis (hypnotherapy), osteopathy, and acupuncture. They found very few statistically significant differences in the students' attitudes to the five therapies. Furnham and colleagues compared the attitudes to CAM of both medical and social science students. They found few differences between them and that both took a strongly 'psychological' approach to health, believing that psychological factors were often the cause of illness. Both were supportive, and skeptical, of some aspects of OM. However, they had more positive attitudes to CAM. Compared to GPs, they believed that CAM practitioners were more sympathetic, had more time to listen, were more sensitive on emotional issues, and were better at explaining treatments. Both student groups seemed particularly positive toward dietary and exercise treatments.

Differences in the Consultation between CAM and Orthodox Medicine

Is the popularity of CAM and its powerful placebo effect due to the often fundamental and dramatic differences between the

stereotypic CAM and OM consultation? There is only a very limited amount of research in this area.

Is it possible to generalize? Is there indeed such a thing as a typical consultation? Is the variation within each group (i.e., CAM vs OM) different from/greater than the variation between each group? The differences between the consultations of an aromatherapist compared to an osteopath or a psychiatrist compared with an orthopedic surgeon consults are considerable. Indeed, there may be different 'schools of thought' that result in different types/styles of consultations within each CAM or OM specialty. Then, there may be differences depending on the biography, demographics, and training of the individual practitioner. A typical consultation may be hard to define.

Consultations are so varied that any generalizations about the difference are only stereotypical, possibly misleading or meaningless.

Yet patients and practitioners acknowledge, even celebrate, the particular and peculiar approach to the consultation. Wyatt and Furnham (2010) compared 16 different criteria on which these two may differ and may in part explain the popularity of CAM. GPs all too often have too little time, may be perceived as patronizing, and may not examine (touch) the patient. Further, patients are often not asked the full set of questions they expect to be asked for a 'full' diagnosis. In short, they are not treated like a modern adult consumer. CAM practitioners have longer consultations and appreciate patients' need to talk, to be examined/touched, etc. The question is how the traditional/average CAM consultation is different from (better than) the traditional orthodox consultation. It is possible to compare and contrast the typical GP and CAM consultation across a number of variables (history-taking approach, language used, patient role, decision-making process, bedside manner, etc.) to show how different they are, which may account for the popularity of the latter. Research is needed to confirm the view that it is very much the nature of the consultation that both differentiates CAM from OM and makes it attractive.

Why Do People Use CAM?

There is some evidence that frequent CAM users are more health conscious and believe more strongly that they can influence their own state of health, both by lifestyle and through maintaining a psychological equilibrium. CAM patients appear to have less faith in 'provider control,' that is, in the ability of medicine (specifically orthodox doctors) to resolve problems of ill health. Patients with cancer using CAM were more likely to believe that cancer was preventable through diet, stress reduction, and environmental changes and that patients should take an active role in their own health.

1. People shop for health. They want to use all possible (and affordable) options in health care. People are not loyal to a brand, to OM, or any particular therapy. They shop, try out, and experiment. CAM is therefore to many just another product/service. The question is how the particular brand offers something quite different that no other product or service offers. This raises the question as to what makes an individual 'brand loyal'; that is loyal to a therapy, a therapist, or indeed a place of treatment.
2. People want a cure without side effects or pain. This may offer a very strong, unique selling point for homeopathy over herbalism, acupuncture, etc. because of the scare stories about poisoning with herbs or minerals, and pain/infection with acupuncture. It is, for instance, the 'gentleness' of homeopathy and its dilutions that may be particularly attractive to people. The possible contradiction between being harmless and effective is often not confronted.
3. Because they have chronic illnesses or conditions they have difficulty living with. Many patients with chronic painful conditions or addictions have tried many other cures. They turn to CAM sometimes as a last hope. Some therapies have a powerful psychological component, particularly those associated with touch (i.e., massage, reflexology).
4. Because they are disappointed by the traditional orthodox consultation. There are many reasons for patients' disappointment with OM, but it seems that the nature and style of the consultation is the primary explanation of this.
5. Because patients want to learn more about self-care (fitness, wellness, and prevention). OM is seen as narrow and disease (complaint) orientated, which aims to destroy, demolish, or suppress 'sickening forces,' through things such as chemical therapies and surgery. But many people prefer an emphasis on natural restorative processes on how to strengthen the vitalizing health-promoting forces. The emphasis is quite different – illness vs. wellness. Psychologists have long recognized this. CAM is often seen as restorative, balancing, natural, and preventative, which fits in with the particular zeitgeist.
6. Patients believe in the 'holistic' message. It seems obvious to most patients that lifestyle, personal relationships, and work operate together and simultaneously to have an impact on health. Equally they believe that there are many and manifold signs of wellness and illness from digestion, sleep patterns, and body appearance to more subtle nonverbal signs associated with gait, balance, and body odor. The implication is that the diagnostic interview needs to have questions about all aspects of the person's life not only their physical symptoms.

Who Seeks CAM?

It is foolhardy to talk about the 'typical' patients as CAM rejoices in differences, individuality, and the uniqueness of people's lives. However, there are patterns and a higher probability that particular types of people are likely to seek out, use, and benefit from CAM.

Demography: CAM patients are more likely to be women rather than men, aged 30–40 years rather than older or younger, middle rather than working class, well educated, and urban rather than rural.

Medical History: First, patients seeking CAM have chronic problems rather than acute. Second, their health problems are often nonspecific or have a psychological component. Third, many patients have a 'thick file' in the sense that their interest in health issues has led them to seek out various remedies from many different sources.

Beliefs, Attitudes, and Values: To a large extent, it seems the CAM practitioners have tapped into the zeitgeist of people's beliefs about health. Many patients seem to be sympathetic with green issues, ideas, and understanding. These include environmentalism, one-world-ism, and antimaterialism. Pro-CAM beliefs may also include issues of inequality, alienation, and social exclusion. CAM patients also seem to be interested in general consumer affairs and may even belong to bodies that lobby in favor of a certain position. They appear to be sensitive to consumer rights, bad practice, and poor treatment. CAM patients appear to be particularly interested in the 'life of the mind.' They certainly believe the maxim of "a healthy mind in a healthy body." CAM patients are, because of their own medical condition, likely to be very empathic to the plight of others, and hostile to the 'uncaring' attitude of certain specialists (e.g., surgeon).

Health and Illness: Mental Representations in Different Cultures

Abstract

Mental representations of *health* and *illness* are thought processes that guide people's response to the threats to their physical and mental well-being. This article will explore how people living in different cultural contexts understand health and illness, and the implications this has for how they subsequently behave. Biomedical approaches will be presented as the dominant model for understanding health and illness in the West. However, comparisons will be made with other frameworks of understanding that are popular in other cultural settings. In this age of globalization, focus is also allocated to considering the costs and benefits to people of having competing ways of understanding health and illness available at onetime.

At the outset it is important to highlight that contemporary understanding about notions of health and illness in the West owe much to the contributions of prominent sociologists working in the mid-to-late twentieth Century. These individuals were particularly interested in how the age of modernity had impacted on the conceptualization of health and illness. Talcott Parsons was a functional sociologist who defined illness as:

> … a state of disturbance in the 'normal' functioning of the total human individual, including both the states of the organism as a biological system and of his personal and social adjustments. It is thus partly biological and partly socially defined.
>
> Parsons, 1951: 431

Parsons viewed illness as a form of social deviance. Parsons coined the phrase *sick role* to capture how those who experience illness are assigned a particular status in human societies so that the social system's stability and cohesion can be maintained. Health on the other hand was defined as:

> State of optimum capacity of an individual for the effective performance of the roles and tasks for which he has been socialized. It is thus defined with reference to the individual's participation in the social system.
>
> Parsons, 1964: 274

Michel Foucault proposed an alternative form of functionalism, which suggested that the medical profession had emerged to replace religion-based discourses that had dominated preceding centuries. He suggested that modernity had resulted in social discipline and influence being driven by secular science rather than religion. Foucault's position was that the medicalization of the body could be understood as a process of social control (Foucault, 1975). Foucault claimed that definitions of normality (health) and deviance (illness) provided people with the vocabulary through which their medical needs were defined. He suggested that the ultimate beneficiary of this discourse was the medical profession (Bilton et al., 2002).

More recently, Turner (1987) has proposed an integrated sociological analysis of health, illness, and medicine by distinguishing between three separate levels of potential focus: the individual (i.e., the experience of illness and disease), the social (i.e., institutional dynamics – Parsons), and the societal (i.e., wider macro or systemic structures – Foucault). The contributions of Parsons, Foucault, and Turner were all made in the context of the biomedical model being the dominant framework for understanding health and illness in the West. In recent years there have been concerted efforts made to globalize biomedical health systems and services. But with this globalization agenda comes the danger of globalizing systems of understanding that clash with local understanding. This has highlighted the importance of understanding health and illness across different cultures.

Cultural Differences in Mental Representations of Health and Illness

Culture has been defined as:

> a set of institutional settings, formal and informal practices, explicit and tacit rules, ways of making sense and presenting one's experience in forms that will influence others.
>
> Kirmayer, 2006: 133

Cultural factors have been highlighted as influencing the decisions that individuals and groups make about health and illness (Angels and Toits, 1987). In this way 'illnesses' can be distinguished from 'diseases' which are defined in terms of biological processes and are culturally invariant (Kleinman, 1980; Good and Good, 1981). Research has indicated that different cultural groups can employ distinctive explanations to account for health and illness. Kleinman (1980) introduced the term *explanatory model* (EM) to capture understanding about the origins of illness endorsed by particular cultural groups. Angels and Toits (1987) state that the structured narratives about health and illness that can emerge from these EMs can become 'overlearned' to such an extent that they are assumed to be objective reality. These narratives, irrespective of their veracity, can exert a strong influence at a societal level on how people think they should behave (Hacking, 1995). A range of

interview measures exist for eliciting narratives and exploring EMs in different cultural contexts e.g., Explanatory Model Interview Catalogue (EMIC; Weiss, 1997), Short Explanatory Model Interview (SEMI: Lloyd et al., 1998), McGill Illness Narrative Interview – MINI (Groleau et al., 2006), and Barts Explanatory Model Inventory (BEMI: Rüdell et al., 2009). The BEMI builds on the strengths of the previous measures and utilizes mixed qualitative and quantitative methods to facilitate the exploration of perceptions of illnesses across different cultural groups.

When considering the potential interplay between culture and EMs, it is important to guard against the misconception that understanding about health and illness will be uniformly similar across a particular cultural group. Pronounced levels of heterogeneity in beliefs/practices can exist within cultures. For example, Angels and Toits (1987) claimed that within particular cultural groups social factors can influence whether 'symptoms' are viewed as atypical. Social changes such as migration or economic downturns can have cultural repercussions that can impact on narratives about health and illness (Angels and Toits, 1987). So, in considering cross-cultural perspectives on health and illness it will be important to be aware of the risk of assuming that beliefs and practices are homogenous across particular cultural groupings.

Reflecting on the multitude of diverse perspectives on health and illness, Phillips and Verhasselt (1994: p. 316) stated:

> … there is evidently neither a single, universally applicable health system nor an agreed view of health as a concept.

As such, the EMs employed by the biomedical model constitute what has been termed an *ethnomedicine*; a way of understanding health and illness unique to a particular cultural grouping. Other major forms of ethnomedicine include: Chinese traditional medicine, Indian medicines (*ayurveda*, *unani*, and *siddha*), and African traditional healing approaches. Chinese medicine is based on the idea that a life force ('qi') flowing through the body on particular meridians maintains health and vitality (Micozzi, 2005). The philosophical underpinnings of ayurvedic medicine propose that 'prana' gives life to the physical body, and that the body, the mind, and the spirit are interconnected (Pole, 2006). Similarly, traditional healing approaches in Africa generally regard the mind, body, and spirit as one (Graham, 2002), with disruptions in this harmony causing illness. Balance is restored by reintegrating the person with his or her community, the earth, and the spiritual world. Whereas biomedical education teaches medical students to eliminate contextual issues from clinical interviews (Good, 1994), these alternative ethnomedicines appear to be more open to the influence of sociocultural factors.

Implications of Cultural Differences in Mental Representations of Health and Illness

Traditional African healing approaches differ from the Western approach in two main ways (Uys, 1989). First, it focuses on the *who* that caused the illness e.g., was it angered ancestors or did a particular individual engage in witchcraft? Secondly, healing is concerned with the total person, which also incorporates close and distant social relationships. The amount of focus afforded to the social milieu of health and illness is likely to be related to the importance that a particular society allocates to the individual compared to the group i.e., individualistic societies versus collectivist societies (Hofstede, 1980). An example of how important social factors can be in the identity of people living in sub-Saharan Africa is provided by the isiZulu concept of *Ubuntu*, which refers to the notion that *a person is a person through other persons*. Liddell et al. (2005) pointed out that Sub-Saharan African societies tend to categorize illness into three different types:

1. Illnesses which are not linked to particular moral or social triggers (e.g., colds and rashes). These types of illness are believed to be caused by chance, and reasons are not pursued as to why the illness has happened (Yamba, 1997).
2. Illnesses which affect people across the globe and were brought to Africa as a result of colonial intrusions onto the continent (Green, 1994).
3. Illnesses which are exclusive to African people irrespective of tribal identity (Ngubane, 1977).

Liddell et al. (2005) also differentiated between two types of causes that people might seek for the occurrence of illness in Africa:

1. A proximate cause, which describes the *method* by which an illness is contracted (Yamba, 1997). For example, believing that an illness is caused by contamination from pollutants is an example of a proximate cause (Ingstad, 1990).
2. An ultimate cause, which describes *why* a particular person contracted the illness. Examples of ultimate causes for illness include witchcraft and sorcery, ancestral vengeance or punishment (Liddell et al., 2005; Ross, 2010).

Pretorius's (2001) work from South Africa, illustrates the types of support that can be available from traditional healers:

1. Herbalists who are referred to locally as *Izinyangas*
2. *Sangomas* who operate within a religious supernatural context.
3. The faith healers who integrate Christian ritual and traditional practices.

Traditional healers tend to be more geographically accessible to people than the centers offering Western biomedicine (Freeman and Mots, 1992). Although some have argued that traditional healers are a viable alternative when primary health care is unavailable or costly (Puckree et al., 2002; Aitken, 2003), these forms of traditional healing remain poorly regulated (Morris, 2001). In addition, there are risks of serious biomedical complications e.g., rectal mucosal shedding from the use of certain emetics (Ellis, 1996), toxicity from ingestion of substances (Jacobs, 1993), and septicemia and/or death stemming from the use of unsterilized knives for scarification and circumcision (Kale, 1995; Kuse, 1997). Advice from traditional healers may also contradict that given by proponents of biomedical models of illness. For example, Ross (2010) points out that some traditional healers advise people living with HIV/AIDS to take only traditional herbs rather than

antiretroviral medication. However, there is also scope for integrating traditional understanding about health and illness with biomedical approaches. For example, resistance to condom use in some parts of Africa has been addressed by practitioners describing HIV infection as the work of an evil spirit which can be tricked by condom use (Treichler, 1999).

Pluralism is a term used to describe the adoption of multiple medical systems by a particular population. Factors that impact on whether someone opts for biomedicine or traditional healing include: treatment cost (Broom et al., 2009), concerns about how other people will perceive their treatment choice (Crandon-Malamud, 1991), and whether each interaction with a particular type of practitioner is perceived to provide a fresh opportunity to find a solution to the problem (Orr, 2012). However, pluralism is not necessarily always a positive development. Broom et al. (2009) concluded that medical pluralism in India can actually serve to perpetuate restrictive and discriminatory ideas about human value. Whereas in the West, biomedicine is regarded as transcending politics and cultural factors, the practice of Indian medicine is strongly influenced by sociocultural factors such as caste, class, gender, and religious dynamics (Arnold, 1993; Khan, 2006; Pati and Harrison, 2001). Broom et al. (2009) claimed that the politics of aging, along with the patriarchal nature of Indian society, contribute to biomedical interventions being prioritized for younger people and for males. So pluralism may serve to perpetuate and amplify inequality and inequities in health provision to particular sections of the population.

In recent times there has been a proliferation in the availability of information about health and illness through the Internet, which has served to enhance opportunities for medical pluralism. The abundance of information (e.g., self-health books) and sign-posting for additional sources of information (e.g., support groups) means that people can engage in a process of constructing and reconstructing narratives which may serve to maintain or alter their sense of self-identity (Giddens, 1991; Hardey, 1999). Bilton et al. (2002) point out that whereas historically doctors relied on people's descriptions to identify illness, this has now been passed over to clinical instruments, or assessment tools. Indeed, people are now in a position to self-diagnose by using books, or Web-based resources. Questions remain about how reliable and valid these assessment tools are, and how appropriate and relevant they are for use across borders of language, beliefs, and practice.

Conclusions

It is clear that conceptualization of health and illness have varied across time and geographies. These conceptualizations have been influenced by the cultural beliefs and practices of people living in these times and geographies. Social change can bring shifts in what is considered illness. As Feierman (1985: p. 73) pointed out:

> … the evolution of health cannot be separated from the broader story of social change.

Social constructionist perspectives have variously viewed notions of health and illness as being related to themes of conformity, deviance, and/or maintaining power differentials between medical professionals and the public. Today, people across the world draw on diverse EMs to understand health and illness. Culturally defined differences in beliefs and practices about notions of health and illness have led to the development of particular ethnomedicines including biomedicine, ayurveda, Chinese traditional medicine, and a range of African traditional healing approaches. It is important to appreciate that even within particular cultures there will be great heterogeneity in how people understand concepts of health and illness. We live in increasingly cultural diverse populations, and with this come demands for greater pluralism in the services offered to support health and illness. The choice of support that people might seek will be influenced by the: EMs that people employ, cost, perceived effectiveness, and concerns about what others might think of their choice. Pluralism offers people choices about how they understand illnesses and seek support for these illnesses. However, in some contexts, pluralism can be used to perpetuate political agendas and lead to a tiered system of support that serves to discriminate against sections of the population. The Internet is serving to enhance opportunities for pluralism by providing individuals with a wealth of perspectives and information on health and illness. This is giving rise to increasingly eclectic narratives about mental health, narratives that have the potential to, in turn, dynamically shape expectations about how people should think, feel, and behave when healthy and when ill.

Abstract

Images of health, illness, and healing are key media through which societies and groups struggle with central values and beliefs and negotiate social and political progress. The invention and implementation of techniques of health improvement have taken on many forms, including epidemic control, disease eradication, and combinations of environmental and individual behavioral change and medical advance. Yet definitions of health depend on normative and oftentimes conflicting values and contexts, which themselves are influenced by various transformations in economy and polity, science and technology, and culture. Such variables shape the conditions of health and are in turn affected by it. In attending to such reciprocal processes, anthropologists have demonstrated that health as an experience is irreducible to a set of strict criteria of physiological and mental competence or to a set of cultural differences. Only through concrete understandings of particular worlds of well-being and suffering and the way they are shaped by local histories and political economies can we possibly come to terms with the complex dimensions that protect or undermine human health. Health, seen in this way, is a construction as well as a contested way of being in the world.

Health and health practices are part of the inmost complexities of social existence, permeating the domains of politics, economics, and religion and almost always connected with dimensions that go beyond the body, such as interpersonal, family, and community relationships. Health is at once an end and a means. Explanations of the causes and patterns of health and disease often convey value judgments, senses of right and wrong and of accountability and blame, as well as reveal what is morally at stake in definitions of health and its failures. Medical anthropological studies have built upon historical and cultural analyses over a long period of time that indicate an array of difference with respect to the metaphors and meanings that signify health. These studies have emphasized cultural fabrics that give coherence and depth to these meanings such that cosmology and ethical traditions come to define the body in states of sickness and well-being.

Anthropological studies focus on local contexts where health and illness are recognized and responded to. Such studies also trace the effects of global flows of commodities, information, finance, images, people, and pathogens on such worlds. Anthropologists have been as interested in the social roots and consequences of health (and illness) as in their cultural representations. But what most particularly characterizes the anthropological perspective is the use of ethnography to understand health, illness, and health care. Anthropological perspectives on health bring together individual and collective realities in the way they are organized, narrated, contested, and in every sense lived as social trajectories (Kleinman, 1995).

What anthropologists have learned through research in different societies is a story of diversity in experiences of health and health care giving, as well as of the ways social relationships and emotional processes interfuse in the mediation of health-relevant experiences. The meanings of health range from holistic and organic interpretations to hyperindividualistic ones. While biomedicine has treated health as a separate domain, popular meanings and interpretations of healthy states are often inseparable from other moral, political, and economic domains. Anthropologists have been particularly concerned with the transformations in health as those transformations express differences in power, social position, and social inequality, particularly as experienced by marginal groups and individuals. But in recent years, equal interest has been devoted to studies of health professionals, bureaucrats, and scientists who contribute to the public definition of health and health problems. Culture affects health as much through the culture of biomedicine and bureaucratic institutions as through the popular culture; indeed in the age of wide-ranging social media the two are closely related.

Applied medical anthropology addresses issues such as the ones raised and addresses them at the policy level. In heterogeneous societies such as North America and Western Europe, cultural differences continue to matter in the health field in large part because of differences in health conceptions which affect the panoply of health-relevant practices, from popular assessments of risks and responses to them to the uses and misuses of health care resources. Those differences contribute to different health outcomes for people; but they also contribute to different health systems, which are themselves undergoing transformation due to both local and global economic and social changes.

Images of Health and Diverse Experiences of Health

The contemporary world contains impressive variations of images of health, modes of health maintenance, efforts at prevention, and illness experiences. Much of this variation is subsumed under what demographers and epidemiologists have termed the 'health transition.' This phrase refers to an increase in life expectancy, decline in mortality, and overall decrease in infectious diseases in the twentieth century by means of interventions such as vaccinations and dietary improvements. Health status measures have been introduced and are continually revised to develop policy, planning, and evaluation; these measures shape ideas of health and health improvement according to specific indices that promote interventions and

sociobehavioral change. The health transition has also been accompanied by major changes in patterns of morbidity, increases in chronic degenerative diseases, old and new epidemics, and behavioral and mental pathologies and is thus more complex than its original conceptualization (Chen et al., 1994). The very economic, technical, and industrial development that has benefited so many coexists with ongoing massive societal disruptions. Developing countries, for example, are experiencing the social and health costs of rapid urbanization and economic restructuring, costs that are confirmed in statistical increases of preventable disease and chronic illness, and borne in terms of health problems such as infant mortality, life-threatening dehydration, urban violence, and hunger (Scheper-Hughes, 1992; Bourgois, 2002). Such acts as war, political persecution, and homicide contribute to a deliberate production of suffering and death. The era of infectious diseases is by no means past as the spread of HIV/AIDS, multidrug resistant tuberculosis, and other infectious diseases suggest. The collapse of public health measures and treatment regimens, demographic changes, migration, and other human actions intensify the flows and resistance of pathogens. It is through such mechanisms that Paul Farmer has shown the ways social forces alter disease distribution and contribute to the persistence of new microbial conditions; indeed, the way "social forces and processes come to be embodied as biological events" (1999: p. 5). The appearance of these disorders, closely correlated with poverty and social inequality, challenges the notion of a single biological etiology for disease and illustrates that these infectious diseases are mediated by multiple interacting causes that require anthropological inquiry and policy intervention.

The burden of chronic diseases such as heart disease, cancer, stroke, diabetes, and asthma continue to be distributed unevenly across minority groups. Yet statistics also disclose impressive variations. In the United States, for example, there is the so-called Latino Epidemiological Paradox: Latinos, who generally experience a low socioeconomic status, nonetheless, have health outcomes that are either equal or better than non-Hispanic whites. African Americans, by comparison, experience significantly higher rates of infant mortality, death, diabetes, HIV/AIDS, heart attacks, strokes, and homicides. Differences in levels of institutionalized racism, dietary patterns, and the influence of the Spanish language as a protective barrier have been pointed to as possible explanations for this paradox. Notably, health indices of Latino immigrants worsen from generation to generation in the United States, owing to increased assimilation, a loss of balanced diet, chronic insecurity, as well as limited accessibility of health care services (Hernandez and Charney, 1998; Galvez, 2011; Waldstein, 2010; Holmes, 2013).

The latest cluster of disorders to receive attention in the health transition is the rising rates of substance abuse, violence, psychological trauma, depression, suicide, and related mental health problems (Desjarlais et al., 1995). This group of health problems has increased to epidemic proportions both in developed and developing societies. Anthropological studies indicate that these problems often cluster together in settings of deep poverty and societal breakdown. They are compounded by the fact that services tend to be limited, and health care financing and resources are inadequate. Many psychiatric hospitals in China, Russia, and Latin America and elsewhere continue to rely on a model of care involving prolonged stays in locked wards with antipsychotic medication and maltreatment (Phillips et al., 2013; Gostin and Gable, 2004). Anthropological interventions have gone beyond explication of the 'soft' variables underpinning mental health problems and focus on the ways social, economic, and political contexts shape the formation, distribution, and manifestation of disorders. Thus in the anthropological perspective, health problems and social problems are inseparable; health policies and social policies are viewed as necessary complements in defining criteria and techniques of successful rehabilitation.

Local Variations in Illness and Health

In response to emerging sets of health issues, anthropologists have identified the need for cross-cultural studies of health, healing, and morbidity in local contexts. One thread linking these studies is the importance of understanding patterns of everyday life experience, local knowledge, and social networks that influence personal agency and access to health care, as well as biosocial modes of transmission of diseases. From this perspective, health is seen as not simply originating in individuals themselves or deriving strictly from social forces, but as being engendered in complex interactions between individuals and their social contexts (Leslie and Young, 1992; Good et al., 2010; Inhorn and Wentzell, 2012; Lock and Nguyen, 2010). Such lived responses may occur in contexts of medical pluralism where several therapeutic systems coexist in one cultural setting; or in circumstances in which symptoms are subject to several distinct classifications, diagnoses, and hence, therapeutic courses of action or, once again, where different moral and religious values shape health-promoting and disease-preventing activities related to diet and life style practices and support. By stressing contingencies and by detailing local histories of particular places and peoples undergoing many kinds of social change, ethnographies of health and medicine highlight the way that particular worlds define health and conceive of health equity, while also illuminating the ways in which risks to disease and illness interrelate.

It is not surprising that ethnographers have focused on illness whose event structure is relatively defined. Emphasized is the experience of illness as an interpersonal phenomenon as it is narrated through stories of illness. Ethnographies disclose how suffering is transformed through language and cultural meanings into distinctive illness, narratives whose shared metaphors, voices, and genres represent distinctive experiences and political processes. This transformation, in turn, shapes the lived experience of illness through embodiment of cultural meanings and social relations into body-self processes.

Ethnographers have also focused on different mediating processes – ritual, devotional practices, music, and poetics – that structure a sociosomatic continuum between moral and emotional states. This approach relates to the concept of 'local biologies' by which is meant the different means of relating social worlds and biological processes such that those processes become particularized. Examples include

Margaret Lock's demonstration of fundamental differences in the experiences of menopausal symptoms and the aging process among women in Japan and North America (1993); Lawrence Cohen's contrast of distinctive interpersonal experiences of dementia in India and the West (1998); Rayna Rapp's description of how experiences of class in the United States and technologies of the female reproductive life cycle come to alter experiences of pregnancy, infertility, abortion, and delivery (1999); and Adriana Petryna's analysis of biological citizenship and the deep vulnerabilities left behind by state interventions and failures to intervene in a nuclear crisis (2013).

Ethnographers have also analyzed the trajectory and outcome of illness experiences on the social course of illness. Thus Benedicte Ingstad and Susan Reynolds Whyte (2007) and others have shown how disability is as much a product of social definitions and restrictions and opportunities of access as it is a physical or functional limitation or disease, thus turning disability into an experience of potential wholeness and health. Other anthropologists have investigated societal responses to highly stigmatized disorders that respond to feelings of threat with practices aimed at marginalizing sufferers. Still others have studied experiences of chronic conditions like chronic fatigue syndrome, chronic pain syndrome, and fibromyalgia – disorders that are in a limbo of partial or minimal authorization where patients feel discredited or discreditable because of the lack of social legitimacy. Research here shows how patients often resist biomedical responses that are perceived as undermining and delegitimating.

More recently, this area of research has expanded well beyond biomedically defined conditions to include a variety of forms of violence – structural, political, domestic – that represent significant threats to health. Here researchers of violence have shown how different societal idioms of those institutions authorized to deal with social problems – legal, welfare, religious, and of course medical – construct distinctive objects of programs and policies that not only differ greatly, but that coerce different courses of health and disease and outcomes of these conditions (Biehl, 2013; Das, 2006; Farmer, 2004; Han, 2012; James, 2010; Bourgois and Schonberg, 2009). Perhaps the largest field of anthropological inquiry has examined the varieties of community healing systems that parallel state institutions. Studies of herbalists, shamans, and other folk practitioners (and practices) illustrate how experience is manipulated, how meaning is negotiated, and how illness comes to serve some societal ends such as social control, cultural remembering, and political resistance. The point being that the collective significance of illnesses goes beyond individual and even familial concerns and plays a role in how societies remember, how social reality is legitimated, and how social worlds change (Adams, 2013; Biehl, 2007; Dilger and Luig, 2010; Hyde, 2007; Livingston, 2012; Kohrman, 2005; Langwick, 2010; Nguyen, 2010; Rivkin-Fish, 2005; Wendland, 2010).

The anthropology of health and medicine largely began as an applied field. There continues to be important segments of the field that seek application in public health and biomedical settings and in the policy arena. Such applied work classically demonstrated that health beliefs could either facilitate or become a substantial barrier to implementing policies and progress (Paul, 1955). More recently, anthropologists have engaged the nongovernmental, administrative, and political dimensions of international health agencies and the policy development process indicating how community organization can positively inform health and social programs in arenas such as HIV/AIDS prevention, cancer or infectious disease control, and family planning (Hahn, 1999). Hence, anthropology has moved from a stance of critique of application to a stance of generating novel applications combining anthropological knowledge and public health technologies to enhance health.

Nowhere is this better seen than in the recent attention to global health initiatives. Such initiatives and programs are booming in the United States and have begun also to displace earlier framings of the field (such as 'international health'). Anthropologists are engaged in empirical and theoretical investigations of global health-related programs and epistemologies and are concerned with the actual impacts of these initiatives on medical care, citizenship, and governance (Farmer et al., 2013; Biehl and Petryna, 2013; Hahn and Inhorn, 2008; Singer and Derrick Hodge, 2010; Janes and Corbett, 2009; Nichter, 2008; Rylko-Bauer et al., 2009). Multiple theoretical ideas, methods, and epistemic frameworks cohabit within the broad enterprise of global health. Anthropologists engaging this field have pointed to the tensions between private markets and public interests in the design of collective and individual health. They attend to the breakdowns in public health systems and to the myriad social determinants of health (such as education, water, sanitation, vector control, air pollution, and violence prevention) that make people vulnerable to disease in the first place, as well as the humanitarian, legal, and experimental settings that make up new infrastructures of humanitarianism, survival, and global patient life – and where law and medicine become deeply personal (Redfield, 2013; Petryna, 2009; Fassin, 2009; Ticktin, 2011). Through intervention into these fields and analysis of how global health programs are implemented, received, or improvised, anthropologists have pointed to the limits of traditional evidence-making practices and models of care delivery, as well as to the moral values underpinning large-scale health designs. In measuring the value that interventions have for people, anthropologists have illustrated both intended and unintended consequences of these interventions on those in need and how they are 'contested or resisted at different social scales,' thus challenging the certainties of planners and implementers alike.

Culture of Biomedicine

Distinctions between health and disease or illness are patterned according to norms. Norms of health and disease often emerge through a combination of statistics patterns, public consensus around desirable health outcomes, and social definitions and responses to deviance (Mechanic, 1997). The extent to which biomedical norms have achieved a position of preeminence in health care systems and definitions of disease is undeniable. Biomedicine's success in eradicating certain diseases and prolonging life shows that norms, however value-laden and socially constructed they may be, can indeed be health-enhancing (DelVecchio Good, 1995). Yet anthropological

studies have questioned biomedicine's reductionism, primary value of efficiency, and authority in mediating interpretations of health, illness, and suffering (Good, 1994; Kleinman, 1995); they point to the fact that physiological measures alone fail to capture the subjective, social, and even racialized dimensions of health (Rouse, 2009; Mattingly, 2010; Montoya, 2011; Fulwiley, 2011; Lee et al., 2008). The growth of biomedicine, its characteristic quality of redefining social problems as health problems needing biomedical intervention, and its global cultural reach have also been analyzed. That biomedicine has been closely allied with the growth of industrial capitalism has led many ethnographers to examine biomedicine as a deep conduit of social regulation and discipline influencing all sectors of life, from definitions of disability to norms of occupational health, to definitions of mental illness and fitness (Turner, 1995; Martin, 2009). This process has led to strong critiques regarding the necessity and indeed at times harmfulness of biomedical interventions, particularly with respect to the unpredictable side effects of technical procedures and drugs used to diagnose and treat patients. Public concerns over medically induced adverse effects (known as iatrogenesis) are reflected in current debates over the consumption of psychiatric drugs by preschool children in the United States, for example. Cross-cultural studies reveal the extent to which this integration with local experience is contested or resisted by highlighting: the many discrepancies between biomedical knowledge and subjective accounts of illness and health; the moral and religious tensions underlying choices of medical systems; and the degree to which distinctions between health and disease are rooted (or uprooted) by global ideologies and beliefs.

Attention to the international political economic context in which biomedicine operates is central to understanding how ideas of health modify, as well as to understanding the modes through which they are integrated as a set of values and practices in local contexts. As with nonbiomedical healing traditions, pharmaceuticals too are a compelling theme in the anthropology of health and medicine because they link individual understandings of disease and therapeutic practice with broader scientific and political–economic regimes of health (Whyte et al., 2002; Petryna et al., 2006; Ecks, 2013). The pharmaceutical industry is the major producer of today's therapeutic armamentarium. In more than 70% of all medical doctor visits in the United States, doctors will prescribe or continue to provide a medication to a patient. On average, two drugs or 'drug mentions' have been documented per medical visit. Sustaining this pill-taking, life is a complex globalized system of drug testing and drug development. In capturing the trajectory of pharmaceuticals (including their regulatory dimensions, clinical testing, industrial production, and mass consumption), anthropologists have made critical inquiries into notions of 'best evidence' as well as changing boundaries between the normal and the pathological in worlds of commodified health. From local and national ethnographic perspectives, they engage the regulatory and international politics of patents and intellectual property and evolving health-as-human-right paradigms and infrastructures, and have assessed the impact of market-driven medicine on cultures of care, public health, and ethics.

Biotechnology and Health

In response to the large influence that public health has achieved in our times, many due to the advances of biomedicine and advances in technology, the power of state action in the public domain, and market forces, health has increasingly become a specialized domain. The history of public health is punctuated by major advances in population-level health in the nineteenth and early twentieth centuries, through sanitary and workplace improvements, housing, and nutrition. In recent years, public health priorities are shifting from social medicine (with its attention to the social determinants of health) to individually targeted health promotion. The launching and completion of the largest biology project ever conceived – the decoding and mapping of the human genome – has already accelerated this process of individualizing health vis-a-vis the genetic profiling of diseases and increased prognostic information. For example, silicon chips embedded with hybrid bits of DNA can test for various genetic conditions in individuals. Such 'self-quantifying' diagnostic tools are refocusing medical practice away from intervention to risk factor analyses and disease prevention.

The diseases individuals might be predisposed to, how they might react to particular medicines, and what health-promoting behaviors they might adopt to prevent future illness are all encompassed in this revolution (Rabinow, 1996; Eisenburg, 1999; Hamdy, 2012; Sanal, 2011; Roberts, 2012; Edmonds, 2010; Brotherton, 2012; Taussig, 2009; Fischer, 2009; Sharp, 2006; Dumit, 2012). Genomic information and the multitude of genomic sequences represent novel, but as yet largely unrealized, targets for therapeutic intervention. In short, the 'life sciences industry' – knowledge of the genetic code and how to manipulate it and therapeutic promises – is transforming diagnostics and intensifying screening for genetic disorders, often state-mandated (Timmermans and Buchbinder, 2012), but it has yet to usher in a new age of personalized treatment. As consumers embrace incremental self-improvement via genomic knowledge, the prospect of widespread genetic testing has prompted concerns about how such information is being used to discriminate against those labeled as predisposed to genetic risks. Historically, such discriminations took the form of restricting or denying insurance coverage or employment. Inherent inequalities of access to health care can also limit the effectiveness of new technologies.

The success of biotechnology highlights the growing demand for health as a market sector. It attests to the power of biomedicine as a rationality in everyday life (in the organization of health care and delivery, policy analysis, legal procedures) that comes up against other forms of knowledge such as religion, and that coexists with older power structures related to family, gender, ethnicity, and class. Health as commodity, to be objectified, bought, and sold in the marketplace has led to new freedoms to pursue health as an individual project, but also raises dilemmas and creates new risks: who is caretaker of genomic information? Who will have access to genetic therapies? These questions highlight some of the dangers regarding the social uses of genetic knowledge in the genomic and postgenomic era; they make it difficult to say what counts as

success in this drive toward health and profits, a drive which has both sacred and secular sources and consequences.

The trade off between benefits to individuals and risks to populations of any given new technology must also be carefully assessed. For example, over a decade ago xenotransplantation promised to end the so-called shortage in donor organs by engineering transplantable animal organs. While breakthrough technologies might save the life of a few, they pose dangers to populations in terms of the resistant viral strains and antibodies that might develop as a result of such transplant procedures. Another example of the way scientific advancement produces new social risks is found in the case of the traffic in human organs. Such traffic has been afforded by the availability of cyclosporine, among other things. This availability, combined with demand for human organs, has turned vulnerable populations in Brazil, South Africa, and India into potential organ suppliers. Inconsistencies across the globe regarding the rights of donors as well as the lack of follow-up care for many of them have lead to prolonged suffering or premature deaths, or both. Processes related to the globalization of the life sciences industry demand ethnographic attention to technical advances in terms of their development and diffusion; patterns of accessibility and differences of improved health outcomes across socioeconomic divides; and new forms of health and vulnerability these advances engender.

As the life sciences redraw human experience and redefine life chances, anthropologist have turned their gaze once again to social relations, namely, to the moral dimensions and necessities of care and caregiving, particularly in the context of chronic disease such as dementia, diabetes, cancer, and addiction and global health and end-of-life care (McLean, 2006; Norwood, 2009; Mol, 2008; Taylor, 2008; Garcia, 2012; Kaufman, 2006; Manderson and Smith-Morris, 2010). Care is fundamental to the managing of illness but it is often taken for granted or undervalued within professional medical practice and broader political and moral economies of health care. Anthropologists have described caregiving as "the close experiential language of actually doing it" (Kleinman, 2009: p. 292). The elderly, disabled, or chronically or terminally ill run the risk of being 'unmade' without the intimate practices of care that protect them as recognized persons. Anthropological studies of caregiving in cancer wards, hospitals, nursing homes, and hospice settings have pointed to the unexpected kin and social networks that sustain openness toward the humanity of the care recipient that an overly technical biomedical approach might foreclose.

Images of health, illness, and healing have become key media, a 'fragile salvation,' through which societies and groups struggle with central values and beliefs, and negotiate social and political progress. The invention and implementation of techniques of health improvement have taken on many forms, including epidemic control, disease eradication, and combinations of environmental and individual behavioral change and medical advance. Yet definitions of health depend on normative and oftentimes conflictual values.

Health as an individual goal coexists with new threats to health worldwide. The spread of advertising for cigarettes or the dumping of expired pharmaceuticals in low-income countries are all part of the globalization of disease. Under such conditions, what was once health, now becomes disease. Health maintenance and promotion, once so influential a concept, can be undermined owing to new political and economic realities.

Contexts of health are themselves undergoing changes and are influenced by transformations in economy and polity, in science and technology, and in culture. These contexts shape the conditions of health and are in turn affected by it. These processes demonstrate that health as an experience is irreducible to a set of norms of physiological and mental activity, or strictly to a set of cultural differences. Only through concrete understandings of particular worlds of suffering and the way they are shaped by local histories and political economies can we possibly come to terms with the complex human dimensions that protect or undermine health. Health, seen in this way, is a construction as well as a contested way of being in the world.

Abstract

A number of psychosocial theories have been developed to predict, explain, and change health behaviors. In this article, six widely used theories are discussed in turn and then compared. They include four continuum theories (the health belief model; protection motivation theory; the theory of planned behavior; and social cognitive theory), one stage theory (the transtheoretical model), and one theory that has both stage and continuum versions (the health action process approach). Common criticisms of these theories are briefly addressed.

The term 'health behavior' is used very broadly in this article to refer to any behavior that influences, or is believed to influence, physical health outcomes, either by increasing or decreasing their risk or severity. A number of psychosocial theories (or models – the two terms are used interchangeably in this article) have been developed to predict, explain, and change such health behaviors. There are two main types: continuum theories and stage theories (Sutton, 2005; Weinstein et al., 1998). Stage theories assume that behavior change involves movement through a sequence of discrete, qualitatively distinct, stages, and that different factors are important at different stages. Continuum theories have a simpler structure. They specify a single prediction equation for behavior; for example, the health belief model (HBM) specifies that behavior is influenced by perceived susceptibility, severity, benefits, and barriers. The difference in structure of these two types of theories has implications for how they are tested and used as the basis for health behavior interventions. An intervention based on a continuum theory should target the determinants of behavior that are specified by the theory, whereas, for a stage theory, different interventions are required for people in different stages to encourage or help them to move to the next stage.

In this article, six theories are discussed in turn and then compared. They include four continuum theories (the HBM; protection motivation theory (PMT); the theory of planned behavior (TPB); and social cognitive theory (SCT)), one stage theory (the transtheoretical model (TTM)), and one theory that has both stage and continuum versions (the health action process approach (HAPA)). Common criticisms of these theories are briefly addressed.

The Health Belief Model

The HBM (Becker, 1974) was developed in the 1950s by a group of social psychologists working in the field of public health who were seeking to explain why some people do not use health services such as immunization and screening. The model is still in common use. There are four core constructs: the first two refer to a particular disease whereas the second two refer to a possible course of action that may reduce the risk or severity of that disease. Perceived susceptibility (or perceived vulnerability) is the individual's perceived risk of contracting the disease if he or she were to continue with the current course of action. Perceived severity refers to the seriousness of the disease and its consequences as perceived by the individual. Perceived benefits refers to the perceived advantages of the alternative course of action including the extent to which it reduces the risk of the disease or the severity of its consequences. Perceived barriers (or perceived costs) refers to the perceived disadvantages of adopting the recommended action as well as perceived obstacles that may prevent or hinder its successful performance. These factors are commonly assumed to combine additively to influence the likelihood of performing the behavior. Thus, high susceptibility, high severity, high benefits, and low barriers are assumed to lead to a high probability of adopting the recommended action. Another factor that is frequently mentioned in connection with the HBM is cues to action (events that trigger behavior), but little empirical work has been conducted on this construct.

There have been several meta-analyses (quantitative reviews) of research using the HBM. The most recent of these (Carpenter, 2010) was the most rigorous and focused on 18 studies that used a longitudinal design in which the HBM variables were measured at time 1 and behavior at time 2. Benefits and barriers were consistently the strongest predictors of behavior, with mean correlations of 0.27 and 0.30, compared with 0.15 for severity and only 0.05 for susceptibility. Several moderators were identified, including the length of time between the measurement of beliefs and behavior (the longer the time, the lower the correlation) and prevention versus treatment behaviors (higher correlations for prevention). Carpenter recommends that researchers should abandon the simple four-variable additive model and instead examine possible mediation and moderation among the variables.

Protection Motivation Theory

PMT (Rogers, 1983; Rogers and Prentice-Dunn, 1997) was originally developed to explain how people respond to fear-arousing health threat communications or 'fear appeals.' It can be regarded as an adaptation of the HBM. Protection motivation refers to the motivation to protect oneself against a health threat; it is usually defined operationally as the intention to adopt the recommended action. Of the determinants of intention specified by the model, the four that have received the most

empirical attention are vulnerability and severity (equivalent to perceived susceptibility and severity in the HBM), response efficacy (the belief that the recommended action is effective in reducing the threat), and perceived self-efficacy (the belief that one can successfully perform the recommended action; Bandura, 1997). Thus, a person will be more motivated to protect himself or herself (i.e., have a stronger intention to adopt the recommended action) to the extent that he or she believes that the threat is likely if the current course of action is continued, that the consequences will be serious if the threat occurs, that the recommended action is effective in reducing the likelihood or the severity of the threat, and that he or she is able to carry out the recommended action.

In many studies using this model (e.g., Wurtele and Maddux, 1987), specific PMT variables are experimentally manipulated in a factorial design and their effects on intention (and sometimes behavior) are measured. In fact, PMT is unique among health behavior theories with respect to the relatively large number of experimental tests that have been conducted.

To date, two meta-analyses of PMT studies have been conducted (Floyd et al., 2000; Milne et al., 2000). The analyses used different study inclusion criteria and different effect size measures. Floyd et al. analyzed 65 studies with about 30 000 research participants, whereas Milne and colleagues included 27 studies with about 8000 participants. There were only 12 studies in common. Both analyses found support for each of the main PMT variables as predictors of intentions and/or behavior. Self-efficacy had the strongest, most consistent, and most robust effect.

The Theory of Planned Behavior

The TPB (Ajzen, 1991, 2006b), an extension of the theory of reasoned action (TRA), developed out of social–psychological research on attitudes and the attitude–behavior relationship. According to the theory, behavior is determined by the strength of the person's intention to perform that behavior and the amount of actual control that the person has over performing the behavior. Perceived behavioral control, similar to Bandura's construct of self-efficacy, refers to the person's perceptions of their ability to perform the behavior and is assumed to reflect actual behavioral control more or less accurately. To the extent that perceived behavioral control is an accurate reflection of actual behavioral control, it can, together with intention, be used to predict behavior.

The strength of a person's intention is determined by three factors: their attitude toward the behavior (their overall evaluation of performing the behavior); their subjective norm (the extent to which they think that important others would want them to perform it); and their perceived behavioral control. Attitude, subjective norm, and perceived behavioral control are each held to be determined by sets of salient (readily accessible) beliefs about the behavior. Attitude toward the behavior is determined by behavioral beliefs about the personal consequences of performing the behavior; subjective norm by normative beliefs about the views of important others; and perceived behavioral control by control beliefs about the presence of factors that may facilitate or impede performance of the behavior.

The TPB has been widely used in observational studies to predict and explain intentions and behavior. Meta-analyses of these studies show that, on average, the TPB explains between 35 and 50% of the variance in intentions and between 26 and 35% of the variance in behavior (Sutton, 2004). To date, the theory has not been widely used to develop behavior change interventions (Sutton, 2010).

Social Cognitive Theory

According to SCT (Bandura, 1986, 1997), behavior is influenced directly by goals and self-efficacy expectations and indirectly by self-efficacy, outcome expectations, and sociostructural factors. Goals are similar to intentions in other theories of health behavior; they determine the amount of effort that the individual invests in changing their behavior and serve as guides to action. Self-efficacy refers to a person's belief in their ability to perform a specific action in a particular situation. Outcome expectations are beliefs regarding the consequences (positive and negative) of performing the behavior. The theory distinguishes between different kinds of outcome expectation. For example, social outcome expectations might include anticipated approval or disapproval from one's partner, whereas self-evaluative outcome expectations refer to anticipated feelings arising from internal standards such as pride in having achieved a change in one's behavior. Finally, the theory incorporates perceived opportunities and barriers, which are assumed to influence goals.

Although SCT includes a number of constructs, the majority of empirical applications of the theory focus on self-efficacy. There is a large body of evidence from observational studies showing that self-efficacy expectations consistently predict behavior (Luszczynska and Schwarzer, 2005). The theory has also been used as the basis for behavior change interventions, again focusing almost exclusively on self-efficacy. According to Bandura (1997), there are several ways of enhancing self-efficacy. These include mastery experiences, in which the person gains confidence by achieving a modest goal; observation of someone similar to themselves successfully performing a behavior, known as modeling or vicarious learning; and verbal persuasion.

The Health Action Process Approach

The HAPA (Schwarzer, 2008) exists in both continuum and stage versions and is sometimes described as a 'hybrid' model. The model incorporates several constructs from other theories of health behavior, including risk perception, outcome expectancies, self-efficacy, and intention. Unlike other theories, it specifies different types of self-efficacy. For example, maintenance (or coping) self-efficacy refers to optimistic beliefs about one's ability to deal with barriers that arise during the maintenance period, and recovery self-efficacy refers to self-efficacy to get back on track after experiencing a failure, lapse, or setback. Another HAPA construct that does not occur in the other theories discussed in this article is action planning (or action plans), which refers to having

made a detailed plan regarding when, where, and how to carry out the target behavior.

Different versions of the model have been tested in longitudinal observational studies. In a typical application of the HAPA model, the constructs are measured on two or three occasions and structural equation modeling is used to test a prespecified causal model. For example, Schwarzer and Luszczynska (2008; Study 2) measured risk perception, positive outcome expectancies, pre-action self-efficacy and intention at time 1, and maintenance self-efficacy, planning, recovery self-efficacy, and behavior (high-fat diet) at time 2, 2 months later. Among other links, the model specified that risk perception, positive outcome expectancies, and pre-action self-efficacy directly influenced intention to reduce fatty foods; planning mediated the intention–behavior relationship; and planning and recovery self-efficacy directly influenced behavior.

These models, and the findings from such model tests, are often interpreted in terms of phases. For example, the part of the model that deals with determinants of intention is referred to as the motivational phase and the mediation of the intention–behavior link is referred to as the postintentional or volitional phase. However, the HAPA as specified and tested in such studies is a continuum theory, similar in structure to the TPB, for example (Sutton, 2005, 2008).

Several recent studies have specified the HAPA as an explicit stage theory. For example, in a study of fruit and vegetable intake, Wiedemann et al. (2009) used a staging algorithm to categorize participants into three stages (pre-intenders, intenders, and actors) and examined predictors of stage transitions between two time points.

The Transtheoretical Model

The TTM (Prochaska et al., 1992) is the dominant stage theory in the health behavior field. It developed from studies of the processes of change in psychotherapy and smoking cessation. Smoking still accounts for the majority of applications of the model but it has been applied to a wide range of other health behaviors, including condom use, exercise, sunscreen use, and healthy eating (Prochaska and Velicer, 1997). Although it is often referred to simply as the stages of change model, the TTM includes 15 different theoretical constructs drawn from different theories of behavior change. These include the stages of change (which provide the basic organizing principle), the 10 processes of change, the perceived pros and cons of changing, and self-efficacy and temptation. The TTM was an attempt to integrate these different constructs in a single comprehensive framework – hence the name transtheoretical.

The version of the TTM used most widely in recent years specifies five stages: pre-contemplation, contemplation, preparation, action, and maintenance (DiClemente et al., 1991). Using a 'staging algorithm,' participants are classified into stages on the basis of their responses to a small number of questionnaire items. Prochaska et al. (1992) represented the stages of change as a spiral. People start at the bottom in pre-contemplation. They then move through the stages in order (contemplation, preparation, action, maintenance) but may relapse to an earlier stage. They may cycle and recycle through the stages several times before achieving successful long-term behavior change.

Of the other constructs in the TTM, the 10 processes of change refer to the things that people think and do to help them move through the stages, the pros and cons are the perceived advantages and disadvantages of changing, self-efficacy is borrowed from Bandura's SCT, and temptation is a related concept that refers to the degree to which a person expects to feel tempted to lapse in different situations.

Although the TTM is still enormously popular, it has attracted a lot of criticism in recent years, culminating in a call for the model to be abandoned (West, 2005). The problems include lack of standardization of measures, particularly of the central construct of stages of change; logical flaws in current staging algorithms; inadequate specification of the causal relationships among the different constructs; misinterpretation of cross-sectional data on stages of change; and confusion concerning the nature of stage models and how they should be tested. (Herzog, 2008; Sutton, 2005). However, although the TTM cannot be recommended in its present form, the notion that behavior change involves movement through a sequence of qualitative stages is an important idea that deserves further consideration.

Comparison of Theories

Aside from the distinction between stage and continuum theories, the theories outlined earlier show a number of important similarities and differences. Some constructs are common to more than one theory. For example, perceived susceptibility or perceived vulnerability occurs in the HBM, PMT, and the HAPA. Other constructs appear to be very similar, for example, perceived behavioral control and self-efficacy. Resolution of current controversies concerning the extent of overlap between such constructs requires the development of clear definitions, so that similar constructs can be distinguished on conceptual grounds, and more frequent tests of discriminant validity to investigate whether sets of apparently similar measures are tapping the same or different constructs.

The theories also differ in the extent to which the constructs and the causal relationships among them are clearly specified. Of the four, the TPB is the most highly specified (though there are still some ambiguities; Sutton, 2004). Another advantage of the TPB is that there exist clear recommendations for how the constructs should be operationalized (Ajzen, 2006a). In addition, Ajzen emphasizes the principle of compatibility. Put simply, this states that for maximum prediction the measures of all the constructs in the model should use the same wording to define the target behavior. This principle is not widely applied in research using the other theories. The other theories lack clarity in important respects. The TTM, for example, lacks a clear specification of the variables that influence each stage transition.

The theories also differ with regard to their scope of application. Key constructs in the HBM and PMT include perceived susceptibility and perceived severity with respect to a given health threat. Although these components can be extended to non-health-related events, for example, the risk of financial

loss, the scope of these theories is necessarily limited by the nature of these two constructs. By contrast, SCT, the TPB, and the TMM are general theories that can be applied to any domain or behavior, for example, voting, career, and purchasing decisions. Stated differently, these theories regard health behaviors (or stage transitions in the case of the TTM) as having the same proximal determinants as other kinds of behavior. Thus, they offer the potential benefit of parsimony.

The theories differ in the degree to which they specify the content of the cognitions they identify. With the TPB, for example, once the behavior of interest has been defined, it is possible to generate questionnaire items for intention and for the direct measures of attitude, subjective norm, and perceived behavioral control. However, in order to generate items for the underlying beliefs, it is recommended that researchers gather information on salient beliefs from members of the target population. These constructs remain 'content-free' until such information is obtained.

Theories of health behavior are often criticized for offering an unrealistically rational account of how people form intentions and make decisions. However, the theories do not imply that individuals always deliberate carefully and always make optimal decisions. People may not be aware of all the options available to them and of all the consequences that may follow from their actions. They may hold incorrect beliefs about the outcomes. They may make rapid decisions based on a few salient considerations. Having made a considered decision (e.g., to go jogging every Sunday morning), they do not necessarily have to weigh up the pros and cons again unless circumstances change; they may simply retrieve their previously formed intention from long-term memory and act on it. Thus, theories of health behavior imply a more limited rationality than is sometimes suggested by their critics.

Theories of health behavior, particularly continuum theories, are also sometimes criticized for being static. This criticism is unfounded: the theories summarize dynamic causal processes. In SCT, for example, changes in self-efficacy and outcome expectations are assumed to produce changes in goals which in turn lead to changes in behavior. Theories of health behavior should specify the time lags involved in these causal processes but most of them do not. However, it is often assumed implicitly that effects on intention are almost instantaneous whereas effects on behavior may be delayed.

Concluding Comments

There is a plethora of theories of health behavior and new theories are continually being developed. Although this can be interpreted as a sign of a field rich in conceptual and theoretical development, it makes it increasingly difficult to accumulate research findings into a coherent body of knowledge. The field would benefit from clearer definition of concepts, greater standardization of measures, more tests of convergent and discriminant validity, greater concentration on a small number of theories, and more empirical comparisons of theories. The vast majority of empirical studies use nonexperimental between-individuals designs. Obtaining repeated measures on the same individuals would allow models to be tested at the individual level. Experimental manipulation of constructs, as has been done in many studies of PMT, would provide stronger evidence of causal effects (Sutton, 2002).

Abstract

This article defines health behaviors and then overviews data on key health behaviors (smoking, diet, exercise/physical activity, health screening, sexual behaviors, and alcohol use). Variations in these behaviors by sociodemographic factors are then considered. The next section addresses the psychological determinants of health behaviors and considers key models, such as the theory of planned behavior, health belief model, and social cognitive theory, and how these models might be integrated. The final section discusses how health behaviors might be changed to improve health outcomes.

Introduction

Much of the interest in behaviors that have important impacts on our health and well-being is based upon two assumptions: that a significant proportion of the mortality from the leading causes of death is caused by the behavior of individuals, and that such behavior is modifiable (Conner and Norman, 2005). Behavior is held to exert its influence on health in three basic ways: by producing direct biological changes; by conveying health risks or protecting against them; or by leading to the early detection or treatment of disease (Baum and Posluszny, 1999).

The Definition of Health Behaviors

Health behaviors have been defined in a variety of ways. For example, Conner and Norman (2005) define them as any activity undertaken for the purpose of preventing or detecting disease, or for improving health and well-being. Gochman (1997) in the *Handbook of Health Behavior Research* defines them as "… behavior patterns, actions and habits that relate to health maintenance, to health restoration and to health improvement" (vol. 1: p. 3). Behaviors within these definitions include medical service usage (e.g., physician visits, vaccination, screening), compliance with medical regimens (e.g., dietary, diabetic, antihypertensive regimens), and self-directed health behaviors (e.g., diet, exercise, smoking, alcohol consumption). Each has received considerable attention from social and behavioral researchers and we now have a growing understanding of the factors determining engagement in such behaviors and ways in which such behavior can be changed.

In describing health behaviors it is common to distinguish health-enhancing from health-impairing behaviors. Health-impairing behaviors have harmful effects on health or otherwise predispose individuals to disease and include smoking, excessive alcohol consumption, and high dietary fat consumption. In contrast, engagement in health-enhancing behaviors convey health benefits or otherwise protect individuals from disease and include physical activity and exercise, fruit and vegetable consumption, and condom use in response to the threat of sexually transmitted diseases. A third set of health behaviors focus on detecting potential health problems and include behaviors such as health screening and testicular/breast self-examination.

Key Health Behaviors

Numerous studies have examined the health-behavior–health-outcome relationship. One of the first such studies identified seven features of lifestyle which were associated with lower morbidity and higher subsequent long-term survival: not smoking, moderate alcohol intake, sleeping 7–8 h per night, exercising regularly, maintaining a desirable body weight, avoiding snacks, and eating breakfast regularly (Belloc and Breslow, 1972). Health behaviors also impact upon individuals' quality of life by delaying the onset of chronic disease and extending healthy life span. Smoking, alcohol consumption, diet, gaps in primary care services, and low screening uptake are all significant determinants of poor health, and changing such behaviors should lead to improved health. Health recommendations in countries across the Western world currently emphasize the importance of an increase in fruit and vegetable consumption, a reduction in dietary fat consumption, increased physical activity, and reductions in tobacco, alcohol, and drug use as important for health promotion and disease prevention.

Smoking

Smoking is the health behavior most closely linked with long-term negative health outcomes. Morbidity and mortality from coronary heart disease (CHD) are increased among smokers (Doll et al., 1994). Moreover, there is a strong positive relationship between the number of cigarettes smoked per day and the incidence of CHD (Friedman et al., 1979). Smoking has also been linked to a number of cancers including cancer of the lung, throat, stomach, and bowel as well as a number of more immediate negative health effects such as reduced lung capacity and bronchitis (Royal College of Physicians, 1983). Despite the array of negative health outcomes, smokers often report positive mood effects from smoking and the use of smoking as a strategy for coping with stress.

A variety of studies support the idea that the vast majority of smokers take up this habit as adolescents with 40% of adult smokers having started before they reached 16 years of age (Royal College of Physicians, 1992). The number of people smoking in the USA and UK has shown a steady decline over the past 20 years from over 30% in 1999 to below 20% now (Center for Diseases Control, 2008). Smoking is higher among less educated, lower income, and minority groups (Rigotti,

1989). Those who quit smoking reduce the risk to their health, particularly if they quit before 35 years of age (Doll et al., 1994).

Diet

The impacts of diet upon morbidity and mortality are well established (e.g., USDHHS, 1988). In the Third World, the problems related to diet and health are ones of undernutrition; in the First World, the problems are predominantly linked to overconsumption of food. In Western industrialized countries, excessive fat consumption and insufficient fiber, fruit, and vegetable consumption are related to health problems. In addition, excess consumption of calories combined with insufficient exercise has made obesity a major health problem. Diet has been implicated in cardiovascular diseases (CVDs), stroke and high blood pressure, cancer, diabetes, obesity, osteoporosis, and dental disease.

It is generally agreed that elevated blood cholesterol level is a major risk factor for the development of CVD (Consensus Development Conference on Lowering Blood Cholesterol to Prevent Heart Disease, 1985) with significant proportions of the population in countries in the Western world having cholesterol levels higher than the level considered to be healthy. For example, in the USA, it is estimated that 50% of the adult population is at risk of CHD due to elevated blood cholesterol levels (Sampos et al., 1989). The reduction of blood cholesterol via dietary change is now widely accepted as an important way of tackling CHD. Dietary recommendations include reducing fat in the diet and increasing soluble fiber intake. However, their impact upon cholesterol levels may be limited.

Physical Activity/Exercise

The potential health benefits of engaging in physical activity and regular exercise include reduced cardiovascular morbidity and mortality, lowered blood pressure, and the increased metabolism of carbohydrates and fats, as well as a range of psychological benefits such as improved self-esteem, positive mood states, and reduced life stress and anxiety. Nevertheless, many adults in Europe (Office for National Statistics, 2006) and the US (USDHHS, 1996) fail to meet physical activity recommendations. For example, the General Household Survey (1989) indicated that only one in three men and one in five women in the UK participate in any sport or recreational physical activity. Moreover, the Allied Dunbar Fitness Survey (1992) of 6000 English adults reported that only one in six adults had engaged in any physical activity that would have been likely to benefit their health (i.e., for 20 min or more at a moderate or vigorous level) in the previous 4 weeks. Participation in regular physical activity and exercise is strongly related to a number of sociodemographic variables. In particular, young people, males, and those from higher socioeconomic status groups are more likely to engage in regular physical activity and exercise.

Health Screening

Individuals may seek to protect their health by participating in various screening programs, which attempt to detect disease at an early, or asymptomatic, stage. In the UK, screening programs have been set up for various diseases including anemia, diabetes, bronchitis, and various cancers (e.g., cervical, bowel, and breast cancers). Taking the example of cervical screening (or PAP testing), it is estimated that if women were screened every 3 years, the cervical cancer mortality rate could be reduced by 70–95% (Greenwald and Sondik, 1986). Research from the UK shows that between 10 and 32% of eligible women remain unscreened (National Audit Office, 1998), while in the USA the number of unscreened women ranges from 13 to 30% (Ruchlin, 1997). Participation tends to be negatively related to age, and positively related to education level and socioeconomic status.

Sexual Behaviors

Sexual behaviors are considered health behaviors because of their impact upon the spread of sexually transmitted infections such as gonorrhea and syphilis. More recently, the role of sexual behaviors in the spread of the human immunodeficiency virus (HIV) has been a focus of attention. While early health education campaigns emphasized the need to reduce the number of sexual partners or avoid particular sexual practices (e.g., anal sex, penetrative sex), more recently the focus has been upon the use of condoms during penetrative sex to reduce the risk of HIV transmission. Condom use is particularly recommended for those with multiple partners or those who do not know their partners' sexual history. For these reasons, much of the health advice concerning condom use has been focused on young people.

There seems to be considerable variation in the use of condoms in response to the threat of HIV/AIDS, although systematic condom use is not widespread even among single heterosexuals. For example, 78% of respondents in an American study declared they did not always use a condom during sexual intercourse (Choi and Catania, 1996). A Canadian study among a population aged 15 years and older reported similar findings with 28% of respondents reporting not having used a condom during their last sexual intercourse with an occasional partner (Health Canada, 1998). In a European study, among respondents who had more than one partner in the past year, only 52% of the men and 41% of the women declared having used a condom at least once (Guiguet et al., 1994).

Alcohol Use

Moderate alcohol consumption has been linked to positive health outcomes. However, high alcohol consumption has been linked to a range of negative health outcomes including high blood pressure, heart disease, and cirrhosis of the liver. High levels of alcohol consumption have also been associated with accidents, injuries, suicides, crime, domestic violence, rape, murder, and unsafe sex (British Medical Journal, 1982). While many of the adverse effects of high alcohol consumption are due to continued heavy drinking (e.g., cirrhosis of the liver, heart disease), others are more specifically related to excessive alcohol consumption in a single drinking session (e.g., accidents, violence).

The General Household Survey (1992) reported that the average weekly consumption of alcohol in the UK was 15.9

units (1 unit = 1 glass of wine or 1 measure of spirits or 0.5 pints of beer) for men and 5.4 for women. In addition, 27% of men and 11% of women were drinking more than the recommended weekly sensible limits (21 units for men, 14 units for women). Heavy drinking is more likely among younger age groups. In a survey of 12 000 Welsh adults, Moore et al. (1994) reported that 31.1% of drinkers aged 18–24 engaged in binge-drinking (i.e., drinking half the recommended weekly consumption of alcohol in a single session) at least once a week.

Relationship of Health Behaviors to Sociodemographic Factors

A clearer understanding of why individuals perform health behaviors might assist in the development of interventions to help individuals gain health benefits. A variety of factors have been found to account for individual differences in the performance of health behaviors. Demographic variables show reliable associations with the performance of health behaviors (e.g., age, gender, ethnic status). For example, there is a nonlinear relationship between many health behaviors and age, with high incidences of many health-risking behaviors such as smoking in young adults and much lower incidences in children and older adults (Blaxter, 1990). Such behaviors also vary by gender, with females being generally less likely to smoke, consume large amounts of alcohol, engage in regular exercise, but more likely to monitor their diet, take vitamins, and engage in dental care (Waldron, 1988). Differences by socioeconomic status are also apparent for behaviors such as diet, exercise, alcohol consumption, and smoking (e.g., Blaxter, 1990) with increases in health-risking behaviors and decreases in health-protective behaviors in lower socioeconomic status groups.

Generally speaking, younger, wealthier, and better-educated individuals are more likely to practice health protective behaviors. Access to medical care has been found to influence the use of such health services (e.g., Black Report, 1988) and may explain some socioeconomic status differences in health behaviors. These factors may interact with other influences such as levels of stress and social support. Higher levels of stress and/or fewer resources are associated with health-risking behaviors such as smoking and alcohol abuse (Adler and Matthews, 1994). Social factors seem to be important in establishing health behaviors in childhood. Parent, sibling, and peer influences are important, for example, in the initiation of smoking. Cultural values also have a major impact, for instance, in determining the number of women exercising in a particular culture. Steptoe and Wardle (1992) report that between 34 and 95% of women in their European student sample had exercised in the past 14 days.

Understanding the Distribution/Prevalence of Health Behaviors

A considerable body of social and behavioral research has examined individual variables explaining sociodemographic differences in performance of health behaviors. An assumption is that these variables may be more readily modifiable in attempts to change behavior. For example, personality variables such as conscientiousness have been related to mortality. Conscientiousness refers to the ability to control one's behavior and to complete tasks. Highly conscientious individuals are more organized, careful, dependable, self-disciplined, and achievement-oriented than those low in conscientiousness. There is considerable evidence showing conscientiousness to impact on health behaviors, health outcomes, and even mortality. Friedman et al. (1993) reported that conscientiousness was significantly associated with lower mortality in later life with those high in conscientiousness likely to live longer (by about 2 years), compared to those low in conscientiousness. An important mechanism by which conscientiousness may influence health is through health behaviors. Friedman et al. (1995) showed that the impact of conscientiousness on longevity was partly accounted for by its effect on reducing smoking and alcohol use. A review of work on the relationship between conscientiousness and behavior (Bogg and Roberts, 2004) showed conscientiousness to be positively related to a range of protective health behaviors (e.g., exercise) and negatively related to a range of risky health behaviors (e.g., smoking).

Thoughts and feelings about a health behavior (or health cognitions) also determine whether or not an individual practices health behaviors and may explain how other factors influence behavior. Knowledge about behavior–health links is an important factor in an informed choice concerning health behaviors. Various health cognitions have been studied including perceptions of health risk, efficacy of behaviors in influencing this risk, social pressures to perform the behavior, and control over performance of the behavior. The relative importance of various health cognitions in determining who performs various health behaviors constitutes the basis of several different models. Such models have been labeled social cognition models (SCMs) because of their focus on health cognitions as the primary determinant of individual social behaviors. These SCMs provide a basis for understanding the determinants of behavior and behavior change. Each of these models emphasizes the rationality of human behavior and assumes that behavior is based upon elaborate, but subjective, cost/benefit analysis of the likely outcomes of differing courses of action. It is assumed that individuals generally aim to maximize benefits and minimize costs in selecting a behavior. The effects of sociodemographic variables on health behavior are mediated by health cognitions in these models, although direct and moderated relationships are reported (Conner et al., 2013).

Health Belief Model

The health belief model (HBM) outlines two types of health beliefs that make a behavior in response to illness more or less likely (Abraham and Sheeran, 2005): perceptions of the threat of illness and evaluation of the effectiveness of behaviors to counteract this threat. Threat perceptions depend upon the perceived susceptibility to the illness and the perceived severity of the consequences of the illness. Together these variables determine the likelihood of the individual following a health-related action, although their effect is modified by

demographic variables, social pressure, and personality. The particular action undertaken is determined by the evaluation of the possible alternatives. This behavioral evaluation depends upon beliefs concerning the benefits or efficacy of the health behavior and the perceived costs or barriers to performing the behavior. Hence, individuals are likely to follow a particular health behavior if they believe themselves to be susceptible to a particular condition or illness, which they consider to be serious, and believe the benefits of the behavior undertaken to counteract the condition or illness outweigh the costs. It is assumed that this whole process is set in motion by cues to action. Cues to action include a diverse range of triggers to the individual taking action and are commonly divided into factors that are internal (e.g., physical symptoms) or external (e.g., mass media campaigns, advice from others) to the individual. Other influences upon the performance of health behaviors, such as demographic factors or psychological characteristics (e.g., personality, peer pressure, perceived control over behavior), are assumed to exert their effect via changes in the components of the HBM.

Theory of Planned Behavior

The theory of planned behavior (TPB) was developed by social psychologists and has been widely employed to health behaviors (Ajzen, 1991; McEachan et al., 2011). The TPB specifies the influences that determine the individual's decision to follow a particular behavior. Within the TPB, the determinants of behavior are intentions to engage in that behavior and perceived behavioral control (PBC) over that behavior. Intentions represent a person's motivation. The construct is conceptualized as an individual's conscious plan or decision to exert effort in order to engage in a particular behavior. PBC is a person's expectancy that performance of the behavior is within his or her control or confidence that he or she can perform the behavior. Intentions are determined by three variables. The first is attitudes, which are an individual's overall evaluation of the behavior. The second is subjective norms, which consist of a person's beliefs about whether significant others think he or she should engage in the behavior. The third is PBC. Recent revisions to the TPB have suggested that attitudes may divide into instrumental and affective components and subjective norms may divide into injunctive and descriptive norms while PBC may divide into perceived confidence and perceived control (Conner and Sparks, 2005).

The attitude, subjective norm, and PBC components are determined by underlying beliefs. Attitude is a function of a person's salient behavioral beliefs, which represent perceived likely consequences of the behavior (e.g., taking exercise will reduce my risk of heart disease). Subjective norm is a function of normative beliefs, which represent perceptions of specific salient others' preferences about whether one should or should not engage in a behavior (e.g., my family think I should take exercise). PBC is based on beliefs concerning access to the necessary resources and opportunities to perform the behavior successfully (e.g., I have easy access to a place where I can exercise). So, according to the TPB, individuals are likely to engage in a health behavior if they believe that the behavior will lead to particular outcomes which they value, if they believe that people whose views they value think they should carry out the behavior, and if they feel that they have the necessary resources and opportunities to perform the behavior.

Social Cognitive Theory

In social cognitive theory (SCT; Bandura, 1982), behavior is held to be determined by four factors: goals, outcome expectancies, self-efficacy, and sociostructural variables. Goals are plans to act and can be conceived of as intentions to perform the behavior (see Luszczynska and Schwarzer, 2005). Outcome expectancies are similar to behavioral beliefs in the TPB but here are split into physical, social, and self-evaluative depending on the nature of the outcomes considered. Self-efficacy is the belief that a behavior is or is not within an individual's control and is usually assessed as the degree of confidence the individual has that he or she could still perform the behavior in the face of various obstacles (and is similar to PBC in the TPB; e.g., "I am confident that I can refrain from smoking, even if someone offers me a cigarette"). Sociostructural variables are factors assumed to facilitate or inhibit the performance of a behavior and affect behavior via changing goals (e.g., impediments or opportunities associated with particular living conditions, health systems, political, economic, or environmental systems). They are assumed to inform goal setting and be influenced by self-efficacy.

Self-efficacy is one of the most powerful predictors of health behavior (Bandura, 1997). Individuals with a strong sense of self-efficacy are believed to develop stronger intentions to act, to expend more effort to achieve their goals, and to persist longer in the face of barriers and impediments. Perceived self-efficacy is therefore believed to play a crucial role in the determination of health behavior.

Integrated Models of Health Behavior

Models like the HBM, TPB, and SCT show several similarities but also a number of key differences. One approach to combining these models is to consider developing an integrated model. This may be valuable given the overlap in cognitions considered by different models. For example, it is widely accepted that the key cognitions influencing behavior are intention, self-efficacy, and outcome expectancies (or attitudes). One attempt at integration suggested that there were eight key variables determining behavior (Fishbein et al., 2001). The variables are organized into two groups. The first group includes variables viewed as necessary and sufficient determinants of behavior. For behavior to occur an individual must:

- have a strong intention to perform the behavior;
- have the necessary skills to perform the behavior; and
- experience an absence of environmental constraints that could prevent enactment of the behavior.

The second group of variables primarily influences behavior through intention. A strong intention to act is likely to occur when an individual:

- perceives the advantages (or benefits) of performing the behavior to outweigh the perceived disadvantages (or costs);

- perceives the social (normative) pressure to perform the behavior to be greater than that not to perform the behavior;
- believes that the behavior is consistent with his or her self-image;
- anticipates the emotional reaction to performing the behavior to be more positive than negative; and
- has high levels of self-efficacy.

Changing Health Behaviors

The above models detail the key social cognitive determinants of health behavior. To the extent that these models outline the key determinants, interventions, which target these variables should lead to associated changes in behavior. For example, enhancing feelings of self-efficacy could be one means to encourage health behavior change. As Bandura (1997) outlines, there are four main sources of self-efficacy, each of which could be addressed in interventions. First, individuals can develop feelings of self-efficacy from personal mastery experience (e.g., it may be possible to split a behavior into various subgoals, such that the easiest subgoals are achieved before more difficult tasks are attempted). Second, individuals may develop feelings of self-efficacy through observing other people succeed on a task (i.e., vicarious experience). Third, it is possible to use standard persuasive techniques to try to instill feelings of self-efficacy. Finally, one's physiological state may be used as a source of information, such that high levels of arousal or anxiety may indicate to the individual that he or she is not capable of performing a given action (e.g., relaxation techniques may be employed to help maintain feelings of self-efficacy). Alternatively interventions might target changing attitudes as a means to change behavior. This might be achieved using persuasive messages designed, for example, to target behavioral beliefs (e.g., Brubaker and Fowler, 1990). A further approach would be to target the anticipated emotional reactions to a behavior again using persuasive messages (e.g., Conner et al., 2011).

Another interesting approach has focused directly on the immediate determinant of behavior in several of these models, namely intentions. Where individuals do have an intention to engage in a health behavior (goal intentions), but are having trouble implementing their intention, forming a specific plan about where and when to act has been found helpful (Gollwitzer and Sheeran, 2006). For example, Conner and Higgins (2010) got adolescents who did not want to become smokers to repeatedly form plans about how to refuse the offer of a cigarette. This was shown to significantly reduce rates of smoking initiation over the next 4 years.

Over the past few years, research has also sought to develop a taxonomy of the different behavior change techniques (BCTs) that have been used in attempts to change health behavior and relate them to existing theory. For example, Abraham and Michie (2008) set out a total of 26 distinct BCTs used in relation to a range of behaviors. A good number of these relate directly to SCMs described earlier (e.g., provide information about the consequences of the behavior) although others set out alternative means to changing behavior (e.g., motivational interviewing).

Conclusions

Health behaviors have important consequences for both the quality and length of life partly via influencing disease outcomes. Nevertheless, there is still considerable variation in who performs these behaviors. SCMs provide one approach to understanding the variation in who performs health behaviors. These models are also useful because they suggest ways to change health behaviors in order to improve health. Research on BCTs has provided useful information on how to change health behaviors and further insights into why individuals perform these behaviors. The next big challenge for social and behavioral research on health behaviors is to demonstrate how theory-based interventions can produce effective and long-lasting behavior change that results in real benefits in terms of morbidity and mortality.

Abstract

Health-related behaviors, such as physical activity, smoking, and healthy eating differ along numerous dimensions (e.g., frequency, volition), requiring various analysis methods. Physiological methods (e.g., salivary cotinine as a biomarker for smoking) offer high accuracy, and low demand characteristics but are comparably cost-intensive. Moreover, behavior-specific biomarkers are rare, preventing routine application. Behavioral observation methods using electronic devices (e.g., smartphones, accelerometers) offer accurate, valid, and effective possibilities for assessing everyday health behaviors. Self-reports on past behavioral frequencies are the most common and least resource demanding; however, irrelevant or biased questions seriously decrease the validity of a survey.

Introduction: Health Behaviors as a Multidimensional Construct

In the field of health psychology, health behaviors are most often defined as behaviors that people engage in to maintain or improve their current health and to avoid illness. These definitions focus on subjective health beliefs as they include any behavior performed to protect, promote, or maintain health, whether or not such behaviors are objectively effective toward that end. In contrast, most empirical public health studies and epidemiological research focus on behaviors which are defined by experts as having a substantial relationship to health. Therefore, the term health behavior has two different connotations. First, a subjective one which focuses on which behaviors laypeople believe might affect their health, and second, an objective one which focuses on what experts evaluate and define as health-affecting behavior. Importantly, lay and expert views of which behaviors are related to health may differ systematically. In addition, studies have typically found only moderate-to-low interrelations between health behaviors (e.g., Cohen-Mansfield and Kivity, 2011; Héroux et al., 2012). For example, drinking and physical activity are often not associated while the former is often related to smoking. One reason why health behaviors and habits are not consistently interrelated is the fact that they differ on a number of dimensions (see **Table 1**) and may be influenced by different factors. Considering the modest link between different health behaviors and the high variability in individual health behavior profiles, health behaviors should not be conceptualized as unidimensional but rather as multidimensional in character (Stefansdottir and Vihjalmsson, 2007).

Furthermore, health behaviors could be examined as antecedents or causes of health status. Such an approach is taken by social epidemiologists. In contrast, health educators are interested in health behaviors as objective dimensions for systematic interventions directed at producing behavioral changes. Finally, as subjects of scientific study, health behaviors are analyzed as consequences or outcomes, as well as correlates of individual factors. For an accurate and reliable measurement of health behaviors it is, therefore, essential to distinguish between their different dimensions and clearly define the topic to be investigated. There are various methods for assessing health behaviors, ranging from self-report to biological indicators.

What People Say: Self-Report Measures

Questionnaires

Questionnaires which assess past behavior frequency for a specific behavior such as food consumption or general behavior patterns such as eating styles are the most commonly used method for measuring health behaviors. There are numerous questionnaires which ask for the average or typical frequency and quantity of alcohol consumption (see Sobell and Sobell, 1995), food intake (see Kristal et al., 1992), or physical activity (see Pereira et al., 1997). The analytic strategy is the same across all *quantity and frequency measures* (QF estimates). The frequency of the reported behavior is multiplied by the quantity (or intensity) of the behavior, and these are summed up to obtain behavior totals. For example, the International Physical Activity Questionnaires (IPAQ), developed under the auspices of the World Health Organization, demonstrate a good reliability among 18- to 65-year-old adults in diverse settings and countries (Craig et al., 2003) and can be administered by telephone interview or self-administration. The long versions of the IPAQ assess sedentary behavior (sitting) as well as physical activity in three different domains (work, travel/transportation, home/garden recreation) for three different intensity levels (vigorous,

moderate, and walking) for the last 7 days or a typical week. The total weekly physical activity can be estimated by weighting the reported minutes per week within each activity category using a Metabolic Equivalent of Task (MET) energy expenditure estimate. In terms of criterion validity, the self-reported IPAQ data show a fair-to-moderate agreement with accelerometers (pooled $\rho = 0.33$ for the long versions and pooled $\rho = 0.30$ for the brief versions, Craig et al., 2003). Likewise, food frequency questionnaires (FFQ) such as the European Prospective Investigation into Cancer and Nutrition (EPIC) questionnaires comprise up to 148 food items eaten during the past year (frequency and portion size) and allow calculations for nutrient intake via computerized software programs that multiply the reported frequency of each food by the amount of nutrient in a serving of that food (Nagel et al., 2007; Bohlscheid-Thomas et al., 1997).

Questionnaires such as quantity and frequency measures (QF estimates) assume that respondents are able and willing to provide accurate information. However, asking questions such as "How many eggs have you eaten during the last year?," or "How many times have you had beer in the past month?" involves a complex answering process (see Schwarz and Oyserman, 2001) requiring that respondents (1) understand the question, (2) identify the relevant behavior episode, (3) retrieve all relevant behavior instances, (4) correctly add up the behavior instances, and (5) map the behavior instances onto the response format.

From this perspective, asking clear questions about meaningful behaviors that allow candid answers is key to obtaining reliable and valid behavioral data (Schwarz and Oyserman, 2001). Thus, asking leading questions, which suggest an expected answer, or loaded questions, which have emotionally laden connotations, can quickly invalidate a survey. In particular, sensitive questions about topics such as illicit drug use or sexual behavior commonly elicit misreporting that it is largely situational. The extent of misreporting depends on whether the respondent has anything embarrassing to report and the design of the questionnaire. Cumulating evidence also indicates that misreporting sensitive topics is a motivated process in which respondents edit the information they report to avoid repercussions from third parties or to avoid embarrassing themselves in the presence of an interviewer (see Tourangeau and Yan, 2007).

In addition to social desirability concerns, lack in shared meaning can seriously invalidate self-reports. The term 'sexual partner,' for instance, may be interpreted in many different ways by the respondents, ranging from describing someone with whom one has experienced orgasm to someone with whom one has shared a bed while naked. Therefore, the target population should be carefully selected because health behaviors have different meanings in different cultures or age groups and the use of questions, which have been designed and validated for example in younger populations, might be inappropriate for older people.

Furthermore, by their very nature, questions about past behaviors assume an accurate memory of events as well as the willingness to report these to a researcher. However, respondents may not recall the actual events, employing instead various cognitive heuristics (rules of thumb) to estimate frequencies. This could result in certain biases. People use different strategies to answer frequency questions over different time spans. Episodic enumeration (recalling and counting individual incidents) is more likely to be used when shorter or more recent time spans are involved in frequency reports, whereas rate-based estimation (projecting the typical rate over the length of the recall period) is more likely to be used when longer time or more distant spans are involved. Reported behavioral frequencies for a year are generally less than 12 times the equivalent frequencies for 1 month. This phenomenon has been coined the time span effect (Hoorens and Harris, 1998). Use of different time spans over or within studies may lead to inconsistent or even misleading results.

In order to support respondents in their recall of relevant behavioral episodes over a designated time period, Sobell and Sobell (1995) developed the *Timeline Followback Method* (TLFB). Respondents are required to provide retrospective estimates of their daily behavior by using a calendar over a certain time period, which can range up to 12 months prior to the interview. In particular, starting with questions about the previous day and then moving further back into the past facilitates more accurate responses (Heesch et al., 2010). With this method, the pattern, variability, and level of physical activity, drinking, or smoking can be profiled, which is especially useful when relatively precise estimates are required or when researchers wish to evaluate specific changes in health behaviors before, during, and after interventions. Alternatively, 24 h recalls (24-HRs) can be used to decrease the recall burden for respondents. For example, the Day Reconstruction Method comprises the systematic reconstruction of activities and experiences of the preceding day with procedures designed to reduce recall biases (Kahneman et al., 2004). Similarly, the Automated Multiple-Pass Method (AMPM) from the US Department of Agriculture is a computer-based dietary intake assessment which uses multiple memory cues with standardized wording to help the respondent remember all of the food consumed in the last 24 hours (Moshfegh et al., 2008). Cumulated evidence shows that 24-HRs outperform FFQs in accurately assessing individual food intake (Illner et al., 2012).

In addition to memory-based information, respondents may use context-based information to make frequency judgments. One context-based heuristic involves the use of information provided by response alternatives in questionnaires. For example, respondents may use the range of the response alternatives provided to them as a frame of reference for estimating their own behavioral frequency (see Schwarz and Oyserman, 2001 for an overview).

Taken together, questionnaires are a very efficient and cost-effective way to collect data on health behavior. Although self-reports are often criticized for evoking the overreporting of health behavior and the underreporting of risk behavior due to social desirability concerns, a respective design of the survey and anonymity can substantially reduce systematic biases (Tourangeau and Yan, 2007). Moreover, questionnaires are suitable for most populations while placing a comparably low burden on respondents and allowing for comparisons between and within populations over time; thus, questionnaires are inherently suited to surveillance systems and large-sample epidemiological surveys. Given that questions are clear and straightforward, answers have been shown to be valid and reliable. They can also be summarized and transformed into

global indices such as the standardized Metabolic Equivalent of Task (MET). Computerized and internet-based questionnaires offer new possibilities for large-scale studies as they are flexible in terms of time and place of administration and simultaneous participation. Moreover, they offer comprehensive possibilities for tailoring questionnaires to subsamples through additional prompts, explanations, and branches with filter questions. They also save time through immediate data entry, reduce coding errors, and offer possibilities for scoring, reporting, and interpreting results. Furthermore, respondents feel more anonymous as no written record exists, and reduced social desirability concerns may allow for increased reporting of sensitive information (see Warren et al., 2010).

Interviews

Unstructured or semistructured interviews are useful qualitative techniques for researchers interested in understanding individuals' cognitive and conceptual models of health behavior and the frames of reference that individuals use to organize health behaviors. Therefore, qualitative methods are mainly concerned with the exploration and analysis of health behavior because they allow the interviewee room to address the issues which he or she feels relevant to the topics being raised by the investigator. For instance, detailed interviews and ethnography could provide insight into subjective and experiential dimensions of those behaviors related to substance misuse. One major disadvantage of qualitative methods is the fact that generality is, by definition, not quantifiable. Furthermore, since anonymity is not possible, the self-reports elicited by interviews may be affected by social desirability biases, resulting in overreporting of socially desirable behavior and underreporting of socially undesirable behavior. The results from the National Household Survey of Drug Abuse (NHSDA) showed that the percentage of respondents reporting marijuana use was higher when questions were self-administered than when they were administered by an interviewer (see Schaeffer, 2000).

Alternatively, one could introduce a 'reality check' to the respondent's account by using the *method of focus groups* (Morgan, 1997). A focus group is a collective, discussion-based interview orchestrated by a moderator who uses the small group setting to achieve a group dynamic to construct a supportive social context that allows respondents to reveal thoughts and behaviors they would normally be reluctant to disclose. While focus groups are mostly conducted in face-to-face settings, computer-based chat programs offer an alternative platform with greater anonymity and where less socially desirable behavior bias affects discussions. Overall, focus groups could be useful for generating information about behaviors that are rarely talked about (e.g., sexual behaviors and drug use).

Behavior Record Methods

Diary log techniques are data collection strategies which gather information in relation to the passage of time. As such, the yielded information is temporally ordered, providing a sequence of events and temporal profile of actions. Diary techniques can be particularly useful when data for one individual are required over a considerable period of time and/or very frequently, such as providing a general estimate of an individual's consumption for assessing smoking behavior, alcohol consumption, or dietary habits. For example, alcohol consumption diaries often include questions about the frequency of consumption, the type of drink taken, and the quantity consumed on each occasion. In comparison to questionnaires, the diary log format minimizes recall biases associated with retrospective reporting, but daily reporting may be more reactive. In addition, diaries could be valuable for providing access to so-called 'intimate' information (e.g., sexual behavior).

Stone and Shiffman (1994) have labeled strategies for collecting respondents' self-reports for their momentary or current state as *Ecological Momentary Assessment* (EMA). EMA studies usually consist of the repeated assessment of participants' momentary state as they go about the tasks of daily life in their natural environment. There are several ways to approach this sampling task. *Interval-contingent* assessments require assessment at regular intervals. One example is the method of *interactive voice response* (IVR), where people with alcohol use disorder are asked to call in on a regular basis to report their drinking to interviewers. Another way is asking individuals to record every episode of smoking, eating, or some other behavior of interest. This *event-contingent* approach, however, may not lead to a representative sample of the participant's general state and requires a clear definition of the triggering event. In contrast, *signal-contingent* sampling supplies participants with an external signal cue, which is usually timed to be emitted at random, to prompt subjects to complete a written assessment or an electronic diary. Beepers, electronic watches, and palmtop computers have been used as signal devices. Smartphones and tablet PCs offer the possibility of texting participants a personalized online questionnaire link (see, for example, www.surveysignal.com) at random or fixed time intervals.

Comparing global retrospective behavior estimates (QF estimates) with the Time-Line Follow-Back (TLFB) and EMA-based behavioral reports shows only a small difference between global and TLFB estimates and favors the validity of EMA data. Shiffman (2009) for example showed that EMA reports averaged about 2.5 cigarettes less than TLFB for the same period while demonstrating a higher interrelation with the biomarker salivary cotinine. Thus, EMA is a method which assesses recent health behaviors more precisely because it minimizes biases of recall. Instead it relies on respondents' experience reports at the moment of inquiry. However, the burden of frequent reporting may limit the application of EMA for certain behaviors or populations.

Image-based assessment methods (Kerr et al., 2012) or barcode scanning (Boissy et al., 2006) using smartphones or Personal Digital Assistants (PDAs) offer less strenuous opportunities to record health behaviors. Boushey and colleagues developed a dietary assessment application on a mobile telephone where participants take images of their foods. These images are sent to a server where food items are identified and the volume of each food is estimated automatically. The data are then indexed with a nutrient database to compute the nutrient content of the foods consumed (see Six et al., 2010; www.tadaproject.org). The analysis of naturalistic images or

scanning of barcodes provides more 'real-world' information on participants' consumption patterns. However, this information is still provided by participants and shares some critical factors with other self-report methods.

Nonreactive (Objective) Measures

Behavior Observation Techniques

Behavioral observation is a widely used method of behavioral assessment. Unlike self-reports or behavior records, which rely on respondents' perceptions of behavior, behavioral observation involves watching and recording the behavior of a person in laboratory or natural environments (e.g., workplace). Therefore, it is commonly assumed that observational data are more objective than are self-reports.

Most methods of behavioral observation provide a wealth of quantitative data, which capture both the current behavioral status and the dynamics of behavior across time and situation. Depending on the nature of the behavior, observers may be interested in any one or combination of several related characteristics. The most common characteristic observed is behavior frequency. Other characteristics include duration and intensity of the behavioral episode. A behavior change agent might be interested in reducing the frequency, intensity, or duration of a problem behavior. Regardless of which characteristic is observed, it is important to measure that characteristic consistently throughout the observation process.

Behavior observation techniques can be applied in the laboratory as well as in the field. In the field, a wealth of indicators can be used to track the target behavior. Observers can simultaneously assess the time people spent eating in restaurants (Rozin et al., 2003) or technological aids like smart cards can be used to record data on eating behavior in cafeterias. Moreover, individual transactions can be recorded by an electronic audit (Lambert et al., 2005) and participants' food intake can automatically be recorded via a wearable miniature camera (Sun et al., 2010). Behavior signatures can also be used to deduce people's behavior by examining their rubbish (e.g., Rathje and Murphy, 2001). Particular to the domain of physical activity, well-established technical tools such as pedometers and accelerometers are available for observation in natural environments. Pedometers are only suitable to measure steps taken while walking, whereas accelerometers provide an objective measure of time spent in different activities of varying intensities and indicate frequency and duration of activities. These tools are easy to wear and allow unobstructed movements while enabling reliable and comprehensive data collection (see Warren et al., 2010). However, standardized measurement protocols (e.g., number of measurement days for determining habitual activity or cut-off points for classifying activity as sedentary, moderate, or vigorous) still need to be developed. Moreover, wearing an accelerometer appears to increase physical activity (Ainsworth, 2009), thus, putting its use as a diagnostic tool into question.

In the laboratory, behavior might be observed as a response to seminaturalistic settings. For example, eating behavior can be triggered through a bogus taste test and the amount of consumed food can be recorded (e.g., Sproesser et al., 2014). In addition, the microstructure of eating, which is nonassessable through self-report, can be assessed by recording the cumulative food intake with an eating monitor (e.g., Kissileff and Guss, 2001) or chewing, swallowing, and arm movements using on-body sensors (see Illner et al., 2012). Likewise, healthy and unhealthy foods might be offered in choice paradigms. Using authentic food replicas ensures a standardization of presented foods while food preparation costs are greatly reduced (Bucher et al., 2011). For certain behaviors, other seminaturalistic measures such as video-based simulation, which involves participants viewing a video film of various situations relating to the task at hand and measuring responses to that task (e.g., a video-simulation measure of drivers' speed choice), might be more feasible. Another possibility for the seminaturalistic measuring of health behaviors has been proposed by Rothman et al. (1993), who offered participants the opportunity to order a free sample of sunscreen and to indicate their preferred protection factor rather than asking for behavioral intention. However, these techniques can only be approximations of 'reality' because they can be confounded with other variables. In the study of Rothman et al. (1993), one could argue that the participants only ordered the sunscreen because it was free.

While behavioral observation techniques could provide ecologically valid measures, which simultaneously satisfy the demands of internal and external validity, they are often impractical for broader samples or complex and habitual health behaviors. In addition, behavioral observation is not always superior to self-report since, for physical activity for example, objective measures alone do not allow for assessment using different qualitative domains. Therefore, for surveys and large-sample epidemiological studies, self-reports are a crucial – and often the only – source of information about health behaviors.

Physiological Measures

Physiological methods can be used on rare occasions. This is the most accurate way to measure alcohol consumption (via blood or urine sampling), drug consumption (via immunoassay, hair or sweat bioassay procedures), habitual dietary intakes (via biochemical markers), or physical activity (via doubly labeled water, through indirect or direct calorimetry or heart rate monitoring).

Bioassay methods are only required when a high level of accuracy about recent health behavior is needed (e.g., for workplace drug testing) or used in addition to self-reported data to provide a means of validating self-reported information (e.g., about recent drug use). However, in some circumstances respondents' belief that their behaviors can be measured physiologically may be sufficient to reduce misreporting.

Not only do physiological methods often place a moderate-to-high burden on respondents but they are comparably expensive and personally intense and therefore impractical in large-sample studies. Despite providing precise measures (e.g., doubly labeled water for total energy expenditure calculated via CO_2 production) they do not provide detailed information on health behavior patterns (e.g., the intensity, frequency and duration of physical activity) or settings (e.g., frequency during leisure time or work hours). Moreover, biomarkers and physiological measures often are not behavior-specific. Doubly

labeled water, for example, does capture all forms of energy expenditure, including physical activity and the thermogenic effects of food. Doubly labeled water therefore overestimates physical activity unless corrections are made (Prince et al., 2008). In a similar vein, heart rate monitors are efficient tools for assessing total energy expenditure, but heart rate is influenced by various factors such as age, body size, mode of exercise, and physical fitness. Also, heart rate lags behind changes in movement and thus intermittent activity patterns might be masked (e.g., in children). As with accelerometry, there is no standard for the heart flex point that allows discrimination between active and inactive phases, which is why heart rate monitoring should only be used to assess time spent in moderate and vigorous activity (see Warren et al., 2010). Due to their complementary qualities, accelerometers and heart rate monitoring are often combined: At lower levels of activity, heart rate monitoring is less accurate at estimating energy expenditure and accelerometers are at their most accurate. Nonwearing times in accelerometers are readily apparent in measured heart rate (see Warren et al., 2010).

Conclusion

If high accuracy is required, health behavior should be assessed by physiological measures. If these are not available, behavioral observation, EMA, or diary techniques are useful. However, they are resource-consuming and often not applicable to field research on large samples or complex, habitual health behaviors. Although memory or motivational biases lead to decreased validity and reliability in self-reports, these can provide very useful information for scientific studies on the consequences of health behaviors. To ascertain the accuracy of self-reports, researchers should consider the different connotations of the questions between different samples and construct the questions carefully in order to reduce autobiographical memory biases and social desirability influences. The selection of the most appropriate measurement tools must be based on well-thought research questions and an understanding of the dimensions of health behavior that are of interest. For intervention studies the chosen method must be sensitive to potential treatment effects. All of the methods presented in this article are useful tools for repeated assessments seeking to uncover changes in health behaviors, e.g., due to intervention. However, short-term fluctuations, for example in substance use, due to environmental (e.g., social settings) and psychological (e.g., mood or stress) influences may affect the psychometric properties of the measures used. Hence, seasonal effects and short-term fluctuations may lead to superficial behavioral changes, which could be misinterpreted by researchers as genuine changes.

As this article demonstrates, the perfect assessment method does not exist and the solution often lies in an adapted combination of different methods.

Health Care: Legal Issues (United States)

Abstract

Medicine and the law are inextricably intertwined. This article summarizes key issues in the realm of health care litigation, ranging from liability of insurers and health care providers to the role of courts in national health care policy-making.

In the United States, health care is primarily a private enterprise, run by nongovernmental organizations. The major actors in the system are private health insurers, private physicians, private medical institutions, and private management companies, none of which historically have had cause to align their interests, particularly in the context of legal liability. Even so, the role of governmental actors in US health care has been growing over the past several decades. The governmental actors involved in US health care are predominantly public insurers, most prominently the programs called Medicare (social health insurance for the aged and disabled) and Medicaid (welfare-based medical insurance for the poor). Medicare has been a stable source of public health insurance for people over the age of 65 years since its inception in 1965. Medicaid, on the other hand, is a much more dynamic program, often growing and changing to accommodate other areas of the law, such as changes in welfare rules, but always covering only the poorest citizens. The federal governmental role is poised to increase even more in coming years due to major health care reform embodied in the Patient Protection and Affordable Care Act (the Affordable Care Act (ACA)), which was signed into law in 2010. This law strives to achieve what many other industrialized nations accomplished decades ago: universal health insurance coverage.

The relationship between law and health care in the United States is multilayered and constantly in flux; health care is ensconced in layers of the law. Private common law concepts overlap with public law and constitutional law theories; health care providers are subject to both federal and state regulation of their activities, especially when public insurance is taken as payment for medical services; the federal and state actors often disagree over which governmental body is properly responsible for and thus has power over health care; each type of health care provider is separately regulated by both state and federal agencies and each is subject to differing mechanisms of liability for negligence, fraud, and the like; and costs rose, while access diminished, all of which contributed to a cacophonous health care system.

This article encapsulates the relationship between law and health care in the United States, with a focus on how courts have responded to challenges to managed care's cost containment innovations and the policy changes that litigation may be creating. One source of important litigation change in the past two decades was both a response to, and a reflection of the transition to, a managed care-influenced health care system. How the courts and legislatures responded to these changes in part determined the limitations of the ambitious cost containment initiatives represented by the heavy administrative role of managed care organizations. The move to managed care also included greater enrollment costs and aggressive strategies to exclude undesirable individuals from insurance policies, leading to high rates of uninsurance and underinsurance. Thus, after discussing legal aspects of managed care, the move toward policy-based litigation that appears to be the wave of the future for health care litigation will be considered.

Law and Health Care: Framing the Issues

The legal and medical systems are inextricably intertwined and have long intersected at many points. Since the early 1800s, medical jurisprudence, where physicians are called as expert witnesses and where the courts act to regulate the quality of medical care, has been an integral part of the growth of the health care enterprise. As Mohr noted, "… medical jurisprudence … figured prominently in early American medical history …; neither subject can be fully understood in its modern context without taking the history of legal medicine into account" (Mohr, 1993: p. 251). As this quote suggests, courts have long influenced health care delivery and payment. Even so, the relationship between law and health care has become ever more manifest and more controversial, especially with the high-profile litigation surrounding the ACA.

Historical View

Acknowledging the ebbs and flows of the relationship between law and medicine, it is arguable that the relationship was essentially stable from the mid-nineteenth century until the mid-1960s (Stryker, 1932). As recently as the late 1960s and the early 1970s, health care attorneys and health care executives had to be concerned with a relatively easy set of legal rules. Both sides could predict the nature and scope of liability litigation because the essential rules establishing the standard of care and the possible types of litigation varied little during this period. A typical court case involved one patient suing one physician, guided by liability rules that reflected judicial deference to physicians in setting the standard of care.

This relative stability was greatly disrupted by two major changes in the health care system: the advent of the managed

care organization and its growth, set off by the Health Maintenance Organization Act of 1973, and the establishment of Medicare and Medicaid in 1965. At both the state and federal levels, all three branches of the legal system – legislatures, executive regulatory agencies, and courts – have persistently been involved in setting health care policy and monitoring health care delivery since the mid-1960s, and the regulatory overlay on the prior, stable, and relatively simple mechanisms of liability has created new meanings for legal issues in health care.

Litigation Context

The framing of the legal issues in the modern managed care era reflects the dramatic changes in the health care system since the mid-1980s and the resulting policy conflicts that have emerged. For many years, courts have actively monitored quality of care through determining the standard of care for medical liability (Jacobson, 1989; Furrow, 1997) and interpreting contractual definitions of medical necessity (Eddy, 1996; Hall and Anderson, 1992). Courts have also been called on to interpret the vast array of state and federal legislation regulating health care delivery, and that set of regulations has grown both wider and deeper as the major federal programs have aged.

In responding to litigation challenging managed care cost containment practices, courts have had to confront the question of what role the judiciary should play in monitoring the health care system relative to legislatures. Courts face the tension of applying common law liability principles to new situations or deferring to elected representatives to set potentially bad or inequitable public policy. In the modern health care environment, courts are asked to distinguish the economic aspects of managed care that order relationships between health plans, physicians, and patients, from the monetary incentives that contribute to below-standard care. The former are more traditionally legislative prerogatives, while the latter are traditionally within the judicial purview. For those cases decided in the courts, judges determine whether the issues should be resolved by contract or tort (civil wrongs such as negligence) law. The difference is that recovery under contract is more difficult and damage awards are lower. What complicates matters is that in managed care, the insurance (i.e., contract) and medical care (i.e., potential negligence) are combined in one entity.

The same questions regarding the role of the judiciary, deference to legislatures, and public policy concerns arise in the context of public insurance mechanisms, but the questions become even more complex. This is because the federal government and the states fight over whose power is primary when making decisions about Medicaid, which is funded and structured by the federal government but administered and supplementally funded by the states, as well as Medicare, which accounts for a large portion of the national budget and thus draws political and economic scrutiny. This means that health care providers get caught in the fight, vying often for fair payment, and also being forced to choose a position among these governmental power struggles. In addition, any misuse of the public insurance funds leads to steep penalties at both the federal and the state levels, leading potentially to both civil and criminal liability.

Liability

Common law liability doctrine has traditionally emerged incrementally to adapt to changing circumstances, taking time for the actual contours of a doctrine of liability to be assessed. Nevertheless, certain themes have emerged in modern health care litigation that are likely to continue to evolve so long as the United States maintains its fragmented health care system.

Despite variation in states' case law, the trend has been that courts apply traditional liability doctrine to managed care entities (Furrow, 1997). For early models of Health Maintenance Organizations, the most restrictive form of managed care, the law had already developed holding them liable for torts (civil wrongs) committed by their employees. The courts have also applied indirect liability doctrines, such as vicarious liability and agency principles, to other managed care organizational forms, which exercise less intense administrative oversight, for malpractice committed by an independent physician.

In determining vicarious liability, courts look to the health insurer's control over the physician or how the entity markets its physicians. The greater the indications of control and the more the organization markets the quality of its physician panel, the greater is the likelihood that the managed care organization will be held vicariously liable. In a leading case, *Boyd v. Albert Einstein Medical Center*, 547 A.2d 1229 (Pa. Super. 1988), the court held that an independent practice association (IPA) could be liable for an individual physician's medical malpractice because the patient reasonably believed that the IPA controlled the physician. The court rejected the IPA's argument that it was not liable because the physician was an independent contractor, holding that the physician could still be an agent with respect to the patient. A key element to managed care liability is whether the managed care organization has sufficient control to override a physician's clinical decisions. This occurs through such mechanisms as utilization review, which allows the insurer to evaluate a physician's medical decisions and deny payment for such care.

Challenges to Cost Containment Practices

Health care accounts for a large percentage of the United States' gross domestic product as well as federal and state budgets, and so cost containment is often part of the national conversation. Of course, this is not so different from other countries with more centralized health care systems, but the spending is harder to control because of the significant role of private actors and their distinct interests. The conflict between population-based cost containment and access for individual health insurance subscribers has created large quantities of case law, all of it complicated by the multiplicity of actors in a given case and the evolving nature of the organizational structures in the health care system. Just as the courts had to adapt medical liability principles to the emergence of hospitals as central to health care delivery in the 1960s, the same process is now underway with regard to the ever-morphing organizational forms that form the umbrella concept of managed care. In addition, many health care providers are aligning their interests, making provider liability more complex as well. Sorting out which party is legally responsible for delayed or denied

care, and the acceptable level of care resulting from cost containment strategies, remains a challenge for both state and federal courts. The idea of rationing is still a tough one for legislatures to swallow, and they have *de facto* deferred rationing to nongovernmental organizations.

Nonetheless, courts have not impeded the implementation of cost containment initiatives exemplified by health maintenance organizations and other forms of managed care (Jacobson, 1999). Courts have upheld cost containment programs, except when such programs are seen as limiting access to life-sustaining treatment. For example, state and federal courts have generally rejected challenges to financial incentives (although some courts have allowed such challenges to proceed to trial), utilization management programs, and contractual challenges to benefit denials.

Few courts have been willing to usurp legislative choices in formulating health care policy or to obstruct the market in organizing and delivering health care services, and some courts specifically deflect to legislature's allegations that managed care incentives violate public policy. One reason for this is that courts have interpreted narrowly a federal law called the Employee Retirement Income Security Act to block state court challenges to cost containment programs that deny health benefit coverage. Another reason is that courts look to contract law to determine the extent of litigating parties' obligations and responsibilities, especially in physicians' litigation against managed care organizations. Although the trend toward contract is neither unlimited nor uniform, it represents a potentially profound shift from the early 1970s, when courts were perceived as protectors of individuals, to the modern era when courts act more as supporters of market-based changes.

Physician Autonomy

Courts have ruled that people who are dissatisfied with managed care, including physicians, should take their case to legislatures. This has represented a dramatic departure from the era when courts deferred to physician dominance. And, physicians had a reasonable expectation that courts would protect the physician–patient relationship from interference by managed care plans. On balance, the essence of the health care system lies with the physician–patient relationship, and courts consistently protected physician dominance in the past (Kapp, 1985; Hall, 1988). But, courts have not done so in the managed care era. To the extent that physicians have been able to secure protections through the courts, it has largely been through fair process requirements and retaining the legal standard of professional care.

The question is why courts are not deferring to physicians; what has changed over time to cause the courts' shift from protecting physician dominance to reinforcing managed care's dominance? One potential answer is that courts respond to changes in the underlying environment. As the nature of health care delivery has changed, it stands to reason that courts would begin to incorporate those changes. Slowly but surely, courts have internalized cost containment goals in developing legal doctrine, rather than ensuring the primacy of the physician–patient relationship.

Nevertheless, state legislatures have responded to physicians' complaints by implementing protective regulations, which are now also reflected in the federal ACA. State laws have limited some of the cost containment practices that were on the rise in the late 1980s and 1990s, leading to turnabout for managed care organizations. Even if courts were not willing to rein in the financially dominant managed care organizations, some state legislatures have been able to do so. The federal government has followed these states' lead in the ACA by ending certain practices that had led, over time, to deep inequities in access to and level of coverage by health insurance.

Future Challenges

During the next few years, the legal system will face many questions regarding health care both as implemented and in terms of pure public policy. Major policy questions, such as how to balance the health care access and coverage needs of individual patients with the cost containment goals of the health care system and how to reconcile conflicting social policy goals, seem to more often be decided through judicial processes. This section considers some current and future trends in the overlap between law and medicine.

Balancing Access with Coverage

No easy solution exists for balancing the individual patient's access to health care with conserving health insurers' assets for the entire patient population. Private health insurers in the United States often opt for protecting their economic well-being and that of their shareholders, and patients seek care regardless of its cost – creating constant tension that can lead to life or death litigation.

Despite its name, the ACA leans toward health care access rather than toward cost management. The Act focused on creating a health insurance home for every US citizen because health insurance is the gatekeeper for health care in the United States. To facilitate health insurance coverage, the Act put an end to certain practices, such as policy rescission and preexisting coverage exclusions, which disproportionately excluded the chronically ill, the poor, people of color, and women from health insurance coverage. To ensure a large risk pool to cover the expense of the additional covered lives, the Congress required that every person (with some exceptions) obtain health insurance coverage or pay a tax penalty for failure to carry insurance. In a highly publicized litigation, a private business organization and half of the states challenged the constitutionality of the 'individual mandate' as well as the expansion of the Medicaid program, which helps to provide health coverage to the poor who could not afford private insurance policies, even with federal tax subsidies. These aspects of the ACA were upheld by the US Supreme Court in *National Federation of Independent Business v. Sebelius*, 132 S. Ct. 2566 (2012), although the Medicaid expansion was rendered optional for states when it had been created as a mandatory Medicaid eligibility expansion. But, the win for federal lawmaking may be short lived.

This type of policy-challenging litigation may become the wave of the future. Already, additional challenges to the ACA's health insurance rules are percolating in lower federal courts. Once again, the proper role of the judiciary in health care policy

choices has come to the fore, but now on a much broader scale, as the judiciary has been asked to consider not the decisions of private health executives, but those of the federal legislative and executive branches, which were striving to ameliorate a nationwide, and growing, problem by enacting the ACA.

Social Policy Conflicts

A plethora of legislation has placed health care providers, institutions, and executives in the policy-making cross fire. Some regulations, such as antifraud and abuse measures, are specifically designed to reduce health care costs. Others, such as the Emergency Medical Treatment and Labor Act, are designed to improve access through a point of rescue in the emergency room, regardless of the cost. Taken alone, each individual law is defensible. Taken together, however, the social policy goals of cost containment, improving access to health care, and improving quality of care conflict across statutes and regulations. Complying with all the federal and state laws that apply to health care providers and health insurers may be impossible. And, the multiple layers of law impacting medicine reflect disjointed social policy.

The fundamental policy tensions that underlie such laws are arguably better left to the political branches of government, but courts are mired in litigation regarding health care both on a macro- and a microlevel. Courts' involvement ranges from simple medical liability for negligence cases to major questions about access to courts for Medicaid beneficiaries and the constitutionality of major health care legislation. Each of these cases, whether adjudicating interpersonal conflicts or wholesale social policy, has a ripple effect in health care.

Implications

Other countries may not learn much from the managed care model, as it has created a long stream of litigation and other strife in the United States, resulting in a significant toning down of the original (health maintenance organization) model throughout the early 2000s. On the other hand, it seems likely that most countries will face the need to impose cost constraints on their national health care systems. These choices are already evident in the British and Canadian systems, which are facing the dual pressures of governmental budget concerns and the private sector performing alongside the public system. Reconciling cost containment with institutional stakeholders' objectives, patients' interests, and limited governmental resources takes compromise, careful planning, and often contentious debate. Even then, it can be difficult to ensure that changes are implemented fairly and equitably, and lawmaking by litigation can derail even the most meticulous efforts.

Abstract

The notion of health care markets emerged several decades ago in response to rising costs and limited resources available in health care. Although providing health care to some extent conflicts with established economic principles of functioning markets, attempts were made to strengthen competition, quality, coverage, and choice in the organization of health care. The main current approaches, their promises, and their problems are briefly described, with special emphasis on the United States, Great Britain, and the Netherlands. Robust empirical evidence is still lacking on whether competitive health care markets always result in providing better health outcomes than regulated markets. At the level of research, an econometrically driven health care research might profit from incorporating sociological insights into – and analytical concepts of – organizational functioning.

Origins

'Health care market' is a comparatively new concept of analysis. Health is not an ordinary commodity and therefore was long considered not to be suitable for classical economic analysis. In the 1970s, however, the crisis of the welfare state became apparent, and economical, structural, and social forces started to scrutinize those segments of welfare provision where rising costs were faced with stagnating revenues. The health care sector was no exception to this, in particular as this time period was labeled by some as a 'medical arms race.' Patients were fully covered by (public) insurance, which paid on a fee-for-service basis, and medical providers were motivated to supply more and increasingly costly medical services. Although the empirical evidence of a substantial causal increase of health care costs remains scarce, it goes unsaid that the overall spending for health care continued (and still continues) to rise. Moreover, it became obvious that the increase in the volume of treatment did not fully correspond with an increase in overall health, casting doubt on the efficiency of the health care system's performance. Hence, the concept of 'health care markets' was developed to apply the principles of competition to health care in order to increase efficiency by containing costs while improving quality. A major goal was to incentivize providers to define treatment in terms of overall health improvements rather than in terms of single medical services. This approach started to challenge the professional dominance of physicians who lost some control over the definition of appropriate medical treatments, and it strengthened the role of the payer – who was not identical with the patient – in the health care sector.

Problems of Market Failure

Classical economic thinking for a long time avoided applying the theory of price competition to the health care arena. The exchange between patient and doctor was judged as lacking the basic qualities of efficient markets. These qualities are, among others, a large number of market participants, free market entry and exit, marketability of all products, symmetric information, and zero search costs. In particular, the asymmetry between patients and clinicians (e.g., evaluation of necessity of treatment) on the one hand and the asymmetry between insurer and insurance seeker (e.g., higher likelihood of unhealthy individuals to buy insurance) on the other hand were identified as conditions that distort competition to a substantial extent. Moreover, the structure of the market with regard to health differs from established procedures as there are usually only a few or even only one local health care provider, and the nature of products, that is, every single medical treatment, is virtually a differentiated service that is not retradable. Given these conditions, unregulated competition may or may not lead to a socially desirable outcome. For instance, fixing prices by regulation may result in an overdifferentiation of unimportant product characteristics, as is the case if patients decide to prefer treatment in hospitals with hotellike amenities, although this poorly reflects treatment quality (Gaynor and Vogt, 2000).

Managed Competition as a Possible Solution

To overcome the market failure resulting from the incongruities between economic competition and clinical medicine, Enthoven (1988) developed the theory of managed competition. 'Managed competition' is split into (1) competition between payers for enrollees and (2) competition between hospitals for patients. The payers have now an incentive to contract selectively with hospitals to lower prices and increase quality for their enrollees. Elements of managed care of include (1) government provision of comparative information on health plan quality, (2) definition of minimum package of guaranteed treatments with a means-tested subsidy for low-income individuals, and (3) mandatory risk adjustment schemes between health plans to avoid 'cream skimming' by focusing on young/healthy individuals and avoiding high-cost patients (Cookson et al., 2013). Managed competition was received very well and it was considered by many as the only viable solution to curb health care costs without sacrificing

quality. Nevertheless, critics pointed out several flaws of this concept. Most notably, it implicitly assumes that providers (physicians) are inherently untrustworthy, whereas private payers (managers) are more trustful and, more importantly, more capable of dealing with uncertainty, information asymmetry, and other sources of market failure. Furthermore, managed competition increases marketing costs – that are now necessary to attract patients/enrollees – and it requires a new layer of administration to implement and control services and bills or (changing) clinical behavior. Similar to the concept of managed competition, the concept of 'quasimarkets' was proposed. Quasimarkets developed in health care systems where the government is the only payer and where all citizens are covered by a single (comprehensive) benefit package. Competition between hospitals is often induced by introducing the notion of 'payers' competition,' i.e., by artificially creating (geographically defined) third-party payers, e.g., local trusts, to contract selectively with hospitals. 'Patient-driven competition,' i.e., the principle of allowing patients to freely choose between different hospitals, is thought to motivate hospitals to compete for better quality. However, these two elements may interfere with each other as the payers' ability of contracting selectively is contradicted by the patient's freedom to choose any hospital (Cookson et al., 2013).

Proliferation and Variations

To illustrate, different approaches to health care market's recent developments of health care systems in three countries, the United States, the United Kingdom, and the Netherlands, with markedly distinguished traditions and backgrounds are briefly described.

In the United States, during the early 1980s, Medicare (as a government payer) introduced diagnosis-related groups (DRGs), i.e., prospective payer schemes that reimburse hospitals according to the average cost of a treatment, instead of reimbursing the actual costs of a particular patient. If actual costs are higher than the reimbursed average cost, the hospital realizes an economic loss with a patient. This offers hospitals the incentives to lower average treatment costs and, at the same time to avoid patients with high-cost treatment. Private insurers started to develop similar reimbursement rules. Since the late 1980s, private payers also started to negotiate (discounted) prices with preferred provider organizations, and they registered patients in health maintenance organizations (HMO). HMOs aim to lower prices while trying to ensure the quality of care provided. Despite this promising approach, many HMOs put restrictions on the choice of their providers, and they declined certain treatments. As a result, their public appeal declined. More recently, the Affordable Care Act ('Obamacare') in the United States has passed legislation in 2012, with most provision coming into effect in 2014. This highly debated innovation, considered by some as a groundbreaking structural reform of the world's largest health care market, consists mainly of three elements. First, insurers are not allowed to cap benefits on annual or lifetime basis, and essential benefit packages are defined by the government. Moreover, insurers are not allowed to deny coverage or to charge higher premiums to most individuals with preexisting conditions or adverse health status. Second, the reform stipulates an individual mandate where every individual has to have insurance coverage, either individually or via an employer. Public insurance exchanges are established that rate insurance plans according to the treatments covered in order to increase the quality of information available to the individual buyers. Third, Medicaid is being expanded to cover a higher proportion of individuals. Moreover, insurance contracts will be subsided depending on income.

In 1989, the United Kingdom reformed the centrally administered National Health Service, the world's largest health care organization, by introducing elements of quasimarkets. Internal markets were created, separating providers of health care from the purchasers of health care (Propper et al., 2004). Local bodies contracted an annual fixed amount of treatments from local hospitals for their patient populations – with the intention of maximizing quality for the lowest price. Most elements of the internal markets were dismantled in 1997, however, by the newly elected Labour government, except for the separation between purchases and providers (Cooper et al., 2011). Starting in 2003, a series of market-oriented reforms introduced several new elements. On the payment side, hospitals were reimbursed in a DRG-like system, setting a fixed ex ante price. On the demand side, the concept of patient choice was introduced: instead of being referred by the treating physician, patients were given the choice among at least five different hospitals. This improved patient choice has been, and continues to be, supported by extensive, publicly available comparative information on several quality measures of hospital performance, such as health outcomes or waiting times. The innovation was intended to give hospitals an incentive to lower average treatment costs and yet attract patients through good and further improved quality (Cookson et al., 2013).

In 2006, the Dutch government introduced a mandatory private insurance market. Earlier on, the majority of the population was insured by a public nonprofit system. With this reform, every individual was required to buy private insurance, and private insurers had to accept every applicant. The government subsidizes individuals with low income and organizes a risk adjustment scheme between insures. Insurers are now engaged in mutual competition, and they negotiate with (nonprofit) hospitals' prices through selective contracting (Schut and van de Ven, 2011). This system meets the main criteria proposed by the model of managed competition that Enthoven outlined in the 1970s.

Other countries too transformed or changed their health care sector by introducing elements of 'managed competition,' such as Germany, Switzerland, New Zealand, France, or Sweden.

Empirical Evidence

The following paragraphs can only provide some selective evidence of the role of competition in health care markets, specifically in the current context of increased market competition. The majority of health economic research publications originates from the United States (about one-third of the vast number of published papers (Wagstaff and Culyer, 2012)).

Substantially less research findings are available from Canada, Australia, and the Netherlands, which, nevertheless, document prominent developments in these countries. Recent comprehensive reviews of the empirical evidence include Gaynor (2006), Gaynor and Town (2011), and Propper and Leckie (2011).

Market Structure

The last two decades witnessed a significant structural shift of the US hospital markets. Market structure on the supply side matters, as a low number of competitors in a given market increases their bargaining power, which usually results in overall higher prices (Dranove, 2011). In 2006, 250 of 332 Metropolitan Statistical Areas were classified as 'Highly Concentrated' according to criteria used by the Federal Trade Commission. Mergers and acquisitions were identified as the main driving forces behind this concentration (Town et al., 2006). As for the underlying cause of this consolidation wave among hospitals, many authors point to the rise of managed care and the increase in number of HMOs, among others, and the pressure to improve bargaining power of hospitals (Chernew, 1995; Cutler et al., 2000; Dranove et al., 2002). The causal link, however, may not be as straightforward, and the observed mergers may be a reaction to the anticipated price pressure rather than an actual consequence (Town et al., 2007). Similarly, in the Netherlands the number of hospitals declined between 1997 and 2010 by almost 20%, leading to a high market concentration where half of all Dutch hospitals are now in markets that consist of three hospitals or less. The evidence in England is somewhat mixed: after undergoing a concentration in hospital markets in the late 1990s during the first wave of procompetition reforms, this trend was slightly reversed between 2003 and 2006 as a result of the second reform wave.

A second important area of health care markets beside hospitals concerns physicians and the local organization of their practice. So far, surprisingly little systematic research exists about the structure of local physician markets. Liebhaber and Grossmann (Liebhaber and Grossman, 2007) report that in the United States between 1996 and 1997 and 2004 and 2005 the proportion of solo-/two-physician practices declined from 40.7 to 32.5%. In the same period, the proportion of practicing physicians with an ownership stake declined. Hence, physicians are increasingly working jointly in practices where the number varies between 6 and 50 physicians. These practices, however, are mainly dealing with a single specialty rather than providing multispecialty services, although this latter organizational model may be better suited to support care coordination and quality improvement. In an analysis of the Californian market structure of physician organizations, i.e., the number of groups of organized physicians that contracted with health plans at the county level, it was found that 80% of the 46 counties included in the analysis exhibited a high market concentration (Schneider et al., 2008).

Effect of Competition on Quality

In the past decade, an increasing number of empirical studies investigated the effects of competition on the quality of health care. Usually two price-setting mechanisms are distinguished in these studies: regulated prices and market-determined prices.

In regulated price regimes – such as in England or in the United States for Medicare patients – payers reimburse hospitals with a fixed amount that should be set in such a way that the reimbursement rate is above the cost for an average patient. Several studies in the United States used a measure based on overall market share or on number of hospitals in a local market as a proxy for the degree of competition. Furthermore, these studies included predominantly mortality as a measure of quality of care, whether defined as cause-specific (e.g., coronary heart disease) or all-cause mortality. A majority of these studies found a positive effect of competition on quality (Kessler and Geppert, 2005; Shen, 2003; Tay, 2003), that is, lower mortality in less concentrated markets. This relationship was also observed in England for the changes initiated in 2003 (Cooper et al., 2011, Gaynor et al., 2013). However, some studies find no effect (Mukamel et al., 2001; Shen, 2003) or a reverse relationship for certain local markets (Gowrisankaran and Town, 2003).

In regimes with market-determined prices, little competition took place in the 1960s and the 1970s when consumers were fully covered by insurance and where hospitals were reimbursed for their full cost. This situation changed in the early 1990s with the implementation of policies that strengthened competition, in particular in the US health care system. Studies analyzing these changes showed variable findings: The number of studies reporting an increase in quality (usually lower mortality) when competition is stronger (Abraham et al., 2007; Howard, 2005; Rogowski et al., 2007) was matched by an almost equal number of studies that found a negative effect (Encinosa and Bernard, 2005; Mukamel et al., 2002; Propper et al., 2008).

For the Netherlands, preliminary analyses show that private insurers could curb the price growth for treatments with negotiated prices, i.e., market-determined prices, as compared to regulated prices. However, despite a range of publicly available quality measures, the effects of these developments on the quality of health care are still under study (Schut and van de Ven, 2011).

In the case of regulated prices, economic theory predicts an increase in quality in markets with more competition, as long as prices allow an overall profit. This relationship was confirmed in most studies conducted in England and the United States. For regimes with market-determined prices, it may seem surprising that some studies find an increase in quality, while others find the opposite. However, this is in line with economic theory, which maintains that quality may improve or deteriorate when prices and qualities are determined under market conditions.

Concluding Remarks

It turns out that in competitive markets quality can be higher, while costs are lower. However, this depends on a number of institutional arrangements. For instance, it is important to know who chooses the provider, how prices are set, and to what extent information on quality is available. The last point is crucial in order to overcome the information asymmetry

between provider and patients that is inherent in health care markets. So far, no universally agreed-upon set of indicators measuring overall health care quality is available, e.g., whether to base it on morbidity, mortality, quality of life, or treatment length. A further challenge concerns the definition of best ways of communicating quality information to patients, e.g., through league tables or report cards. It will be important to ensure that patients understand such information and that they incorporate it into their decision making. To rely solely on payer choice in interpreting information on quality measure may not be a good solution, given the vested interests of payers, which may bias their decision. Despite the developments described above, there is still no definite evidence available that competitive health care markets achieve the same or better cost and quality results than regulated health care markets. Against this background, it is difficult to predict potential effects of the recent American health care reform ('Obamacare'), which by its magnitude may challenge established approaches of health care research. Nevertheless, it is of interest to note that the Dutch experience, which shares several elements of with the American health care reform, was confronted with some major problems: both insurers and patients are requiring more meaningful information than currently provided in order to be able to assess the quality of providers. In addition, the amount of competition occurring between insurers might turn out to be weaker than expected, both in terms of attracting enrollees and in terms of bargaining with providers. Most importantly, the Dutch system so far did not achieve total coverage of the population, a main goal of the American health care reform. In the Netherlands, a significant number of people are still uninsured or are defaulting on their insurance premiums (Schut and van de Ven, 2011). However, the interplay between institutions and regulations in the United States is more complex than is the case in the Netherlands as Medicaid – as a single payer system – and the number of privately insured individuals are expected to expand simultaneously.

In a broader perspective, it might be a promising future research approach to health care markets to apply the perspective of economic sociology. The econometrical approaches used to analyze the working of health care markets are very limited as they rarely take into account the individual interactions in health care, such as the relative frequency, complexity, specificity, size, and risk of transactions; the relative quality of information; or the degree of social relationships developing over time. This gap of knowledge is most aptly demonstrated by almost nonexisting research on physician markets. Moreover, empirical studies often ignore the sociological dimensions of the relationships between parties in an economic transaction. These dimensions are typically described in terms of degree of autonomy vs mutual obligation, degree of proximity or distance between partners of a network or organization, size of the organizations or networks, and structure of power relationships. At the macrolevel, the underlying causes of the proliferation and variation of different concepts of health care markets across countries are not well understood. It seems that the prominence of the concept of health care market in part was due to promotion efforts developed by international consulting firms and global institutions, such as the World Bank or the International Monetary Fund. As it is now an international policy movement, many countries are motivated to initiate partial or complete reforms of their health care system, relying on elements of this approach. This will probably remain an ongoing process. The quality and cost outcomes of health markets strongly depend on the institutional structure in which they are embedded and on their delivery procedures whose specific effects are still poorly understood.

Health Care, Rationing of

Abstract

Health care rationing is ubiquitous. It varies from formal approaches designed to allocate limited organs for transplantation to more common strategies and processes that constrain demand for care. Many countries seek to explicitly formulate priorities and translate these through benefit design and other explicit managerial decisions but much rationing is implicit, lacks transparency, and occurs in the routine provision of care. Given unlimited possibilities for expenditure, rationing is inevitable but remains a source of ethical and political controversy.

The term 'rationing' is used with different meanings in health care discussions (Mechanic, 1979). Most generally, it refers to processes of allocation when demand for care exceeds the available supply or the willingness of payers to increase it. In its more narrow application, it refers to how a scarce medical resource, such as hearts, kidneys, or livers, is allocated among competing recipients, only some of whom can receive it. Medical care has always been rationed in both senses, but the concept itself is associated with much affect and denials that rationing occurs.

To the extent that medical care is treated substantially as a commodity, as in the USA, then the market distributes services. Individuals with more comprehensive insurance or the ability to pay out-of-pocket command a greater quantity of and more sophisticated services. But even in market systems, some life and death services in scarce supply transcend the market and are governed by different rationing schemes. In publicly funded medical systems, where most of the population has health care entitlement, whether through national health insurance or a national health service, the availability of services depends on decisions about what services will be financed and their comprehensiveness and intensity (Klein et al., 1996). Some such systems, for example the English National Health Service (NHS), allow competing private systems of care. In contrast, Canada prohibits private provision of services covered by its health insurance program.

Rationing processes and decisions are implemented at different levels of government, by sick funds, large insurance plans, provider organizations such as hospitals, clinics, and health maintenance organizations (HMOs), and at the point of service delivery between clinician and patient. Disagreements are common on where in the hierarchy of health care organization varying types of rationing decisions should be made (macro, meso, or micro) and on appropriate processes for making such decisions (Mechanic, 1997). At each level, rationing may be more or less explicit.

Explicit versus Implicit Rationing

Explicit rationing refers to the detailed specification of how resources will be allocated by a rationing authority. Explicit rationing includes specifying eligibility rules, the specific services to be covered, the amount of coverage for recipients, intervals for receiving services, copayment requirements, the proportion of the budget to be allocated to varying services, the geographic allocation of services, the specific form and location of many services, and appliances and drugs that may or may not be allowed.

Implicit rationing, in contrast, involves setting budgetary limits but allowing the processes of allocation to be worked out at lower organizational levels (Mechanic, 1979). Implicit rationing includes prospective reimbursements or capitation payments. In each case the authority sets the financial limits but then allows the budgeted or capitated entity to establish the processes for decision-making. Total responsibility is sometimes delegated to the lower unit but more typically there are some explicit guidelines and constraints over discretion. All medical systems combine explicit and implicit processes but the balance may differ considerably from one nation to another and within varying national contexts.

Klein et al. (1996) describe a range of strategies for implicitly limiting resources allocated to individuals. These include denial as beneficiaries or for the services claimed; selection of beneficiaries or services on the basis of need or likely success, or demographic characteristics such as age; deflection of care to other sectors or providers; deterrence through bureaucratic barriers such as waiting lists and other delays; diluting services by reducing intensity or restricting specialty care; and premature closure or early discharge.

Concerns About Rationing

Despite general acceptance of the inevitability of rationing, major issues of controversy include who should determine rationing strategies, the openness of decision processes, and whether decisions should be made by managers or by clinicians (New, 1997). Common criticisms are that the implicit rationing processes used are not transparent, often favor the privileged, and result in unequal care for persons of lesser status, education, and sophistication, and with less skill in managing bureaucratic systems (Churchill, 1987). Critics also argue that implicit rationing gives doctors free reign to act on their prejudices. The lack of openness makes it difficult to assess the fairness of decision-making or to allow aggrieved

individuals to successfully appeal exclusions or dilution of care. Implicit rationing is also seen as undermining democratic processes through which communities can bring their preferences to bear in the allocation of important public resources.

A significant difficulty with explicit rationing, in contrast, is that it mobilizes interest groups who seek to affect decisions about coverage. Bringing medical decisions into the public arena energizes a political process and instability in the medical care system (Mechanic, 1995). Using the political process, individuals and/or groups may insist on services that are known to be ineffective or have little value. In contrast, while a particular treatment may be of little value in general, there may be instances, difficult to specify beforehand, where it is appropriate. Explicit rationing cannot, in most instances, accommodate the complex contingencies associated with the use of a particular treatment for an individual patient.

Questions about transparency apply at all levels of decision-making. The criteria used when a national government divides a health budget among regions can have significant consequences. Funds can be allocated politically, on the basis of historical funding, and on the basis of algorithms that take account of population characteristics and dispersion, and varying concepts of health status and need. The availability of facilities and specialists differs widely among population areas and accounts for large variations in expenditures among varying population groups. Nations can seek to bring greater equity among regions, types of services, and even individuals by how they decide to distribute resources.

Within organizations, decisions are made to allocate funding among primary and specialty services, among specialty units, and between medical and related health services. These decisions can have large consequences for the likelihood that a person with a particular need can receive responsive care. At the clinical level, decisions about waiting time, access to specialized services, availability of specialized treatments, or home or hospital treatment can profoundly affect patterns of care. Debate persists as to the extent such decisions should be governed by public discussion and decision-making or left to the discretion of clinicians based on their own professional judgment and experience (Symposium on the Law and Policy of Health Care Rationing, 1992).

Concerns about fairness and facilitating public discussion of priorities would support making practices explicit but there are significant competing concerns. Despite increasing interest in knowledge-based medical practice, much remains uncertain. There is no consensus, in most areas, on standards that apply to a diverse patient population with varying needs and inclinations and unique medical histories. Medical knowledge and practices are rapidly changing and it is uncertain whether explicit standards, once established, can be modified to keep pace with new knowledge. Moreover, medical care is an iterative process with assessment and disease management developing over time. As a complex process of discovery and negotiation, clinical practice is not easily subjected to definitive technical rules.

The notion of explicit decision-making at the level of direct patient care implies that individuals with comparable conditions have similar needs and preferences. But treatment must be flexible and take account of varying social contexts, cultural inclinations, and personal preferences. Treatments of comparable medical effectiveness may have vastly different implications for work and family life, or for comfort under varying circumstances. To treat medical care simply as a technical process, devoid of meanings, preferences, and differential consequences, contributes to dehumanizing medicine, and is unacceptable to many professionals and patients.

Rationing of Specific Resources

Rationing becomes especially salient when problems result, not simply because of the unwillingness to provide more resources or allocate them fairly over some population (which may result in increased illness and death in a statistical sense), but when there is an inability to provide a life-saving resource to all identified individuals who seek it. Such situations involving the allocation of hearts, kidneys, livers, and lungs have been called 'tragic choices' because there are no correct or generally accepted rules for making the decisions as to who receives the resource and who dies (Calabresi and Bobbitt, 1978). A variety of criteria have been applied from one occasion to another, such as allocation by age, by community contribution, by the largest opportunity to benefit, by family circumstances, by ability to cooperate in the treatment process, and many more, but all raise serious ethical conflicts (Elster, 1992). Age is commonly suggested as a suitable criterion (Callahan, 1990) and has been used in making tragic choices (Aaron and Schwartz, 1984) but has been strongly contested. The most satisfactory criteria are medical ones based on likely technical success. But even these criteria do not adequately discriminate among potential beneficiaries, and social judgments and biases inevitably intrude (Halper, 1989). For example, judgments about who can best cooperate in treatment typically give preference to patients with more education, higher intelligence, attractive personality characteristics, and strong social attachments. Such judgments may appear intuitively correct but may be empirically incorrect.

Several analysts have concluded that because the equity issues cannot be resolved intellectually, the fairest mode of allocation is a lottery where persons with comparable medical qualifications have equal chances to be selected. There is little professional or public support for such selections because most people believe that consensual judgments can be made that would improve on any random process. Many rationally constructed strategies of allocation fail also because of public perceptions. The public places greater value on rescuing identified lives than on saving statistical lives (Hadorn, 1991).

Specific Rationing Policies/Practices

As evidence of inequalities in care increases, motivation to distribute limited health resources more equitably has led several countries to address rationing and seek explicit allocation principles and rules. The Oregon rationing program under Medicaid (the USA's federal-state partnership to provide health care to poor and disabled subgroups) was followed with great interest in Europe and perhaps represents the most extreme example of explicit rationing (Leichter, 1999). This effort sought to increase enrollees under its Medicaid program by

selecting to rank treatments consistent with judgments of efficacy and other community values. Through an elaborate process of evaluating condition–treatment pairs, a list was developed that prioritized these pairs. The basic idea was to establish a funding line, given available funds, that excluded from coveraging the lowest ranking condition–treatment pairs. The formal evaluation and ranking process and the use of community meetings to involve consumers and professionals in defining the values for performing the rankings excited the imagination of many outside observers. The process was seen as a rational and fair way to make difficult public decisions about what would and would not be paid for. The Oregon program, however, was not quite what it appeared to be. It was a very public and explicit format for designing the benefit structure. The Oregon Medicaid program is predominantly a managed care program in which HMOs are capitated to provide all funded services. Once capitated, HMOs are free to provide whatever services they deem necessary and need not conform to the list. Thus, the list was more an instrument for bargaining over rates than an explicit set of rules for rationing health care. Early implementation was aided by increased state funding and a favorable economy, which allowed the establishment of acceptable capitation rates. The political sustainability was challenged by fiscal crises that led to large restrictions in coverage (Oberlander, 2007). Oregon is presently rebuilding its Medicaid program with the help of the implementation of national health reform (Affordable Care Act).

The English NHS exemplifies implicit rationing. There are no explicit guaranteed benefits in the NHS but the system seeks to provide all necessary care within the resources available. Care is rationed by the availability of professionals and treatment facilities, by professional decisions about intensity of care and referrals, and by waiting lists for various types of services (Klein et al., 1996; Aaron and Schwartz, 1984). The extraordinary professional discretion within the NHS has led to efforts for greater equity and accountability in resource use. Under recent reforms, health authorities were given purchasing responsibilities and could limit the treatments covered. The political difficulty of doing so explicitly in any but marginal aspects of medical care became evident.

Ethical and Political Issues with Rationing Policies/Practices

A major ethical issue concerns the appropriateness of having physicians, acting as agents of their patients, also responsible for allocation decisions. Traditionally, doctors have been seen as sole agents of their patients, trying to get them what they need. Some believe it is unethical to dilute such agency with allocation responsibilities at the bedside. Others believe that physicians must have a dual responsibility for both their patients and the 'commons.' With the development of HMOs and managed care strategies in the USA, financial incentives are increasingly used to encourage doctors to allocate resources efficiently. There are worries that such incentives create ethical conflicts between the doctor's financial interests and patient care. Such conflicts are also common in unmanaged care when physicians have financial interest in diagnostic and treatment facilities to which they make referrals or in other practices for which they receive financial incentives. Studies have consistently found that such arrangements increase the use of ancillary services (Rodwin, 1993).

There is widespread agreement that it is appropriate and necessary for some governing authority to establish financial constraints on health care expenditures. All national systems have such constraints in place for at least public expenditures. Few believe that it is any longer possible, even in the richest of nations, to provide open-ended financing, allowing physicians to provide all they deem useful. A more-contested issue is the extent to which such an authority, once having established such limits, should specify how the budget should be divided among different types of facilities, modes of care, professional groups, types of patient needs, and treatments and procedures, and by what criteria. The extent of authority given to the nation, as compared with regions, health districts, states, or even smaller population entities, elicits tensions in many contexts. Issues also arise as to whether organizational rationing decisions are best made by management, specialty services, or professionals exercising their best individual judgment.

A possible model that blends explicit and implicit rationing is one emphasizing clinical advocacy within a structure of procedural justice. Such a model would explicitly constrain some clinician and patient decisions through clear rules that are reasonably justified, while also allowing doctors and patients to challenge decisions and argue for revision through dispute resolution mechanisms. Such compromise models offer opportunity for achieving more consensus.

Public views of rationing processes are important because any rationing process that lacks political legitimacy becomes unstable. One of the attractions of the Oregon program was its openness and the participation of large numbers of people. In contrast, in many areas of the USA, the implementation of utilization review (a form of explicit rationing) by managed care organizations overruling physician and patient definition of need has resulted in a significant political backlash. Managed care organizations are finding that transferring risk to professional groups (implicit rationing) kindles less friction than imposing explicit decisions on professionals and patients.

Priority Setting in Modern Nations

Increasingly most modern nations are seeking approaches to better establish priorities as they confront impressive but highly expensive innovations in health technologies and health care and constraints on public budgets. Scandinavia and other European countries have established formal governmental commissions on priorities that have engaged in useful but broad discussion about abstract principles of equity and efficiency but distant from the engaged politics of the many interest groups that affect decisions at the service level. Assessments of these efforts find that actual policy and practice are divorced from the recommendations made by these commissions and other discussions (Sabik and Lie, 2008).

One of the more successful ventures has been the National Institute for Health and Clinical Excellence (NICE) in England, first established in 1999. NICE recommendations determine publicly funded benefits in the NHS. NICE evaluates new health

technologies, pharmaceuticals and interventions, and develops clinical guidelines, taking cost-effectiveness and public and professional input into account. Its analyses and recommendations are focused on new products and approaches, but not long-established but untested ones, and, contrary to expectations, its decisions have not significantly influenced rising health care costs. Yet, NICE's evaluations, not only of efficacy but also cost-effectiveness, remain controversial in many quarters, and new reforms in 2004 introduce the alternative policy encouragement of value-based purchasing (Faden and Chalkidou, 2011).

In the USA, one of the most controversial sections of the Patient Protection and Affordable Care Act of 2010, the extensive health reform known as 'Obama Care,' was the establishment of a new 15-member Independent Payment Advisory Board (IPAD) required to recommend proposals to reduce Medicare spending if expenditures exceed target growth rates, with initial implementation in 2015. These proposals will have force unless the U.S. Congress adopts alternative proposals having an equivalent level of savings or if the President vetoes Congressional action and the veto is sustained. The tension involving this mechanism is illustrated by the prohibition that the Board may not submit proposals that would ration care, increase taxes, change Medicare benefits or eligibility, increase beneficiary premiums and cost-sharing requirements, or reduce low-income subsidies under prescription coverage. Although now law, there is great opposition to the IPAD, particularly among right wing Republicans. The toxicity in the USA of considering rationing explicitly is apparent. Nevertheless, rationing is ubiquitous and will increase in the future in the USA as well as elsewhere around the world.

It will take decades for rationing issues to be sorted out. Health care systems and facilities are experimenting with a range of strategies that may improve decisions and help achieve legitimacy for rationing. These include community representation and involvement in decision-making, surveys to elicit community preferences, focus on evidence-based services, use of treatment guidelines and pathways, involvement of patients in treatment decisions, and implementation of disease management approaches. Rationing and the ability to sustain whatever system is preferred depends on achieving a sufficient level of value consensus so that the difficult choices are widely perceived as fair and responsive to individual need.

Health: Definitions

Abstract

Health etymologically means being whole. Ancient philosophies describe health as a balance between qualities. Hippocrates' view on health, as a balanced mixture of four humors, remained dominant till the sixteenth century. Aristotle stressed development of eudaimonia. From the sixteenth century the biomedical view emerged among physicians, whereas philosophers still stressed the larger context. The World Wars of the twentieth century stimulated the creation of international organizations on health, and the UN preparations led to the WHO. The minutes of these preparations express the idealism with which the WHO was established, as expressed in the WHO definition of health. The WHO aims at monitoring, so a family of classifications was designed, first mainly on diseases, later on functions. The WHO definition met criticism for its absoluteness and being static, and different definitions were proposed by physicians as well as philosophers. Three components are consistent in these proposals: capacity to perform, individual fulfillment, and relation to the social environment.

Etymology

Etymologically the English word 'health' means wholeness, being whole, complete, sound and well. To 'heal' literally means to make whole. Both words go back to the old English word 'hal' and the old German word 'heil.' The ancient Greek word for health was 'euexia,' which means to be in a good condition.

Historical Definitions of Health

Ever since human documentation existed, expressions are found where man differentiates between human states of well-being and 'illnesses,' the latter considered to be abnormal, undesirable and to be healed, if possible. In different ancient philosophies (e.g., Chinese, Indian, Egyptian, or Greek) concepts of illnesses and a state of 'good health' are described, and also the ways how man can achieve good health (Lindeboom, 1982). In these concepts, good health is conceptualized as a state of balance between different 'elements,' which represent different qualities, e.g., the five elements (wood, fire, earth, metal, and water) and the Yin and Yang qualities in Chinese philosophy (Taoism), or the four humors in Greek medicine (black and yellow bile, phlegm, and blood), which originated from knowledge of ancient Egypt and Mesopotamia.

Health is described to be achievable and influenced by lifestyle habits and in certain circumstances, if fate allows, to be influenced by god(s), as mediated by priests in temples. 'Hygeia' was the name of the goddess of health in ancient Greece, the daughter of Asclepius, who represented a good way of living.

Physicians and Philosophers

Over the course of history, physicians as well as philosophers have developed views on the nature of health. Hippocrates (approximately 460–370 BC) (London, 1984), is still considered to be 'the father of Western medicine,' as he was the first to emphasize the importance of a good physical examination of the patient; he created a new paradigm, discriminating in humans four humors: black bile (*melan chole*), yellow bile (*chole*), phlegm (*phlegma*), and blood (*haima*), each corresponding to one of the traditional four elements and temperaments. A healthy situation was the balance between the four humors, and Hippocrates considered diet to be the most influential lifestyle factor in changing the relative proportions between the four, in addition to influences from climate, winds, quality of the water, and the soil.

Historically even more influential Greek-Roman doctor Galenus (131–216) followed and refined the teachings of Hippocrates and described six lifestyle factors, '*res non naturalia*,' which should be in balance in order to maintain health: food and drink (*cibus et potus*), sleep and being awake (*somnus et vigilia)*, light and air (*aer*), secretions and excretions (*secreta et excreta*), work and relaxation (*motus et quies*), and emotions (*affectus animi*).

The 'father of Western philosophy,' Aristotle (384–322 BC) does not discuss 'health' as such, but states that extremes in bodily condition should be avoided and maintaining a proper balance (the mean) is a virtue (Osborne, 2011). Yet, in his ethics he considers '*eudaimonia*' or well-being to be the final goal and good for man. Eudaimonia is an important concept as it is rediscovered in modern views on health. Eudaimonia literally means 'the state of having a good indwelling spirit, a good genius'; in modern translations, it is described as 'happiness' or 'personal well-being.' Eudaimonia is not a static state but a continuous process of development, to fulfill one's potentials and to flourish. This implies self-realization, by which man achieves this happiness and personal well-being.

These views of Hippocrates, Galenus, and Aristotle, about the human potential to be in a state of balance and the virtue of developing oneself, remained highly influential in Western medicine and thinking over fifteen centuries.

From the Sixteenth Century – A New Paradigm Dawns in Medicine

The Physicians' View

A different way of interpreting human health and disease started emerging in medicine when Vesalius (1543) published his studies on the anatomy of the human body. These were based on his own observations by the dissection of bodies, which was considered sacrilege until then. A century later William Harvey (1628) described the system of blood circulation, which was until then thought to be a tidal movement, like ebb and flow. The Galenic humoralism was definitely displaced in 1858, when Rudolph Virchow published his theory on cellular pathology (Virchow, 1858, 1862). In the same period, Semmelweiss discovered the protective effect of disinfective measures against deathly puerperal fever; soon thereafter Pasteur described the existence of bacteria, which he could see in the microscope, and the ways to disarm these (e.g., by pasteurization). From then the paradigms of cell physiology, microbiology, and pathological anatomy became the dominant views in medicine. Diseases were no longer understood as caused by misbalances of qualities, but were to be searched and understood in the physical body, in organs, in cells and in microbes, and should be treated there. Health became the absence of disease (Shorter, 2009).

Parallel to this transition in medical thinking, public health developed in the fast growing cities due to the industrial revolution and by sanitary measures, clean water provision, garbage disposal as well as first vaccinations, infectious diseases like cholera, typhus, and small pox were eradicated and became extinct. The new medical paradigm proved to be effective.

Contemporary Philosophers in the Eighteenth and Nineteenth Century

In the period of this paradigm shift in medical thinking, philosophers still had a broader perspective on health, than as absence of disease. From Goethe (1749–1832) comes the quote "What is the highest virtue on earth? To be healthy? No: to become healthy" (Hygiene Museum Dresden). Nietzsche (1844–1900) discriminated between 'small health' and 'big health' (Verduin, 1998). While 'small health' in his view is concerned with the daily derangements and illnesses with which doctors deal, attaining 'big health' means saying a full YES toward life, with all its insecurities, tragedies and finally death. Big health includes small health, but is connected to growth far beyond that. Rilke (1875–1926) stated "Illness is the means by which my organism frees itself from unfamiliarity. I need just to support my body in being ill, because that is my development" (www.rilke.de/briefe/120804).

Health in the Twentieth Century and the Foundation of the WHO

From the twentieth century, public health started to be organized on a national and international scale, operated by big health organizations (Borowy, 1988). In 1902, the Pan American (international) Sanitar Bureau was founded in Washington DC, while in 1907 the Office International d'Hygiène Publique followed, with headquarters in Paris. In 1913, the Rockefeller Foundation as a first nongovernmental organization was initiated with the aim to enhance the well-being of all mankind.

After World War I, the League of Nations Health Organisation was established, which stood out as the first official body with a global perspective and the broadest work spectrum. In 1919, the League of Red Cross Societies was organized, which developed health programs with an international outlook.

In 1943, a Health Division of the United Nations Relief and Rehabilitation Administration was initiated by the U.S. President Roosevelt "for the relief of victims of war in any area under the control of any of the United Nations through the provision of food, fuel, clothing, shelter and other basic necessities, medical and other essential services." The term 'United Nations' referred to the Allies of World War II.

World War II led to the wish to establish a world organization like the present United Nations, to preserve world peace toward the future. When in 1945 in San Francisco 50 nations met to draft the Charter of the future United Nations, among them there were three medical doctors from Norway, Brazil, and China. They met 1 day for a 'medical lunch,' where the Norwegian Karl Evang suggested "Why don't we start a new health organization?" (WHO, 1988). The idea was to unite the different existing organizations in one single health organization. The men succeeded in having the word 'health' inserted in the Charter of the United Nations and they recommended the general conference to establish an international health organization. This was approved unanimously and this was the very beginning in 1945 of the WHO.

A Technical Preparatory Committee was established to prepare a draft Constitution of the WHO. This committee of 16 men and advisors met in Paris 22 times between March and June 1946. Their work resulted in the draft Constitution of the WHO, which was signed on 22 July 1946 by the representatives of 61 states at the International Health Conference in New York. Thereafter all countries had to ratify the Constitution, which was completed in 1948.

Between 1946 and 1948, an Interim Committee, presided by Andrija Stampar from Yugoslavia, ensured continuity. This Committee decided in favor of Geneva as seat for the headquarters of the WHO, and it was in Geneva at the first World Health Assembly that the Constitution entered into force on 7 April 1948.

The Constitution of the WHO

The Constitution of the WHO starts with the Preamble, stating the principles upon which the whole document is based (WHO, 1948):

> The States parties to this Constitution declare, in conformity with the Charter of the United Nations, that the following principles are basic to the happiness, harmonious relations and security of all peoples:
>
> Health is a state of complete physical, mental and social well-being and not merely the absence of disease or infirmity.
>
> The enjoyment of the highest attainable standard of health is one of the fundamental rights of every human being without

distinction of race, religion, political belief, economic or social condition.
The health of all peoples is fundamental to the attainment of peace and security and is dependent upon the fullest co-operation of individuals and States.
… Etcetera.

The definition of health has a central position in the Preamble Constitution of the WHO. There had been some discussion whether a definition of health should be in the Constitution. Szeming Sze, a public health doctor from China, one of the three who initiated the idea for the WHO and a member of the Technical Preparatory Committee, describes how the phrasing of the definition of health came about (WHO, 1988). Some detail on this process is also to be found in the minutes of the Technical Preparatory Committee (WHO, 1947). A subcommittee of four physicians, Canadian psychiatrist Brock Chisholm (later to become the first Director-General), Argentinian psychiatrist Gregorio Bermann, Joseph Cancik from Czechoslovakia, and Sze himself had 'some pleasant academic discussions' and decided to emphasize mental health as well as the preventive side of health and so they came to the wording of health as not merely the absence of disease. The minutes of the Technical Preparatory Committee describe several preversions of the definition, with terms like 'physical fitness' and 'positive health.'

Idealistic Intentions

The WHO definition of health is, like the Constitution as a whole, phrased very idealistically. One should realize these are formulated in a reaction to the horrors of World War II. The atmosphere in the Preparatory Committee may be characterized by a phrase in the minutes of this Committee where Chisholm is cited with the following phrase: "The world was sick, and the ills from which it was suffering were mainly due to the perversion of man, his inability to live at peace with himself. It was in man himself that the cause of present evils should be sought. The microbe was no longer the main enemy: science was sufficiently advanced to be able to cope with it admirably, if it were not for such barriers as superstition, ignorance, religious intolerance, misery and poverty. These psychological evils must be understood in order that a remedy might be prescribed, and the scope of the task before the Committee, therefore, knew no bounds. For that reason Dr. Chisholm associated himself with the 'visionaries.' What was taking place in these meetings would be of great historical importance if all members aimed at universal and worldwide achievement. To do this, they might find it necessary to bite off more than they could chew, but the alternative was complete chaos. They should do their utmost to bring all the peoples of the world together in the service of physical, social and emotional health."

Chisholm refers to penicillin, which became available for general use, after Fleming had discovered it in 1928. In a time where infectious diseases were still dominant, this discovery nourished great expectations to ban these diseases. Yet, the broadness of the definition of health, beyond the absence of disease, was at the time ground breaking and is owed to this special group of physicians, who directed this process of establishment.

In several charters, declarations and statements the idealistic aims of the WHO were renewed every few years since the inception of the definition of health, (www.who.int/healthpromotion/conferences/en/; www.who.int/trade/glossary/story039/en/). Of these, the best known is the 'Alma Ata Declaration,' which emerged from the UNICEF/WHO Conference on Primary Health Care of 1978, addressing health as a fundamental human right, health inequalities and the connected need for economic and social development; the 'Health for All by the year 2000' declaration of 1981, as target for the WHO; and especially the condensed and strongly formulated 'Ottawa Charter for Health Promotion' of 1986. There the WHO definition was described in connection to the conditions by which this state could be met: "To reach a state of complete physical mental and social wellbeing, an individual or group must be able to identify and to realize aspirations, to satisfy needs, and to change or cope with the environment. Health is, therefore, seen as a resource for everyday life, not the objective of living. Health is a positive concept emphasizing social and personal resources, as well as physical capacities. Therefore, health promotion is not just the responsibility of the health sector, but goes beyond healthy lifestyles to wellbeing." As fundamental "prerequisites for Health are mentioned: peace, shelter, education, food, income, a stable co-system, sustainable resources, social justice and equity." The charter calls for 'building healthy public policy' and the 'creation of supportive environments.'

During the 2013, Helsinki 8th Global Conference on Health Promotion the tone was a somewhat less idealistic and the 'implementation gap' was addressed. It was concluded that the 'Health in All Policies' approach was one of the key domains of shared governance toward health in the twenty-first century. In all these texts, the original definition of health of the WHO was maintained.

Operationalization of Health by the WHO since 1948

The WHO Classification Systems

The WHO intends to monitor population health around the world and is thus in need of health indicators (Chatterji et al., 2002). Yet, the WHO itself recognizes that the definition is not sufficient to develop operational indicators of health. The definition places health in the broad context of well-being in general, whereas health in itself is separate of well-being, yet instrumental for it. Health is first of all an attribute of an individual person and comprises states or conditions of the human body and mind; attempts to measure health must thus include measures of functions of body and mind.

There is general acceptance of describing health states of individuals, in terms of multiple domains and in self-report instruments. For measurement purposes of health status valid, reliable, and comparable indicators are needed. According to the WHO, a measurement instrument requires:

- a classification of health status domains,
- specification of a set of domains necessary and sufficient to describe health states for measurement purposes,

- specification of what is being measured in each domain,
- a common understanding of what is full health versus exceptional talent in any given domain, and
- if it is required, to construct summary measures of average level of population health, a method to place a single cardinal value on the overall level of health associated with a health state defined on multiple domains (Chatterji et al., 2002).

Since 1948, the WHO designed several classification systems, together described as the WHO Family of International Classifications (www.who.int/classifications). At first, the focus was on causes of mortality, diagnoses, and causes for morbidity, for which the International Classification of Diseases (ICD) and Related Health Problems was developed, which is the international standard for epidemiological purposes.

However, gradually thinking about health states evolved and in order not to just evaluate mortality and diseases, but also disabilities, functioning and health states, the International Classification of Functioning, Disability and Health (ICF) (previously the International Classification of Impairments, Disabilities and Handicaps (ICIDH)) was elaborated (**Figure 1**). The ICF measures six domains of activity and participation, by a person's capacity, as well as performance. The gap between capacity and performance is considered to reflect the impact of the actual environment. The ICF goes beyond health condition, functions, activity and participation, and also takes environmental factors into consideration. The domain of personal factors is least elaborated, in fear of 'blaming the victim,' e.g., in cases of health damage through inequalities.

Quality of Life and Well-Being and Health-Related Quality of Life

Objective indicators of health and functioning as specified in the ICF need to be distinguished from a person's subjective appraisal of well-being and quality of life (QoL). It can very well be that a person with impairments still experiences a good QoL; this is called the 'disability paradox' (Faber von et al., 2001). In this context, the WHO identifies 'QoL' as "an individual's perception of their position in life in the context of the culture and value systems in which they live, and in relation to their goals, expectations, standards, and concerns" (Chatterji et al., 2002).

The WHO developed several instruments for measuring well-being and QoL: the WHOQoL-100 (www.who.int/mental_health) with 100 items covering six domains and the WHOQoL-BREF (www.who.int/substance_abuse) with 26 questions in four domains, which are worldwide one of the most widely used instruments for assessing QoL. The short WHO-5 well-being index (www.sayhelp.net) connects well-being mainly to mental health.

General QoL should be distinguished from Health-related QoL (HR-QoL), i.e., QoL perceived in relation to symptoms, impairments, and functions.

For HR-QoL, the best-known measurement instruments (from outside the WHO) are the SF-36, the Health Utility Index (HUI), the Nottingham Health Profile (NHP), and the EQ-5D.

Many more measurement approaches have been developed, like the measurement of QALY's (Quality-adjusted Life Years) or DALY's (Disability-adjusted Life Years), but these will not be described here.

Contemporary Philosophers of the Twentieth and Twenty-First Century on Health

The WHO was designed and further developed mainly by members of the medical profession. Yet 'health' is not a topic that concerns just physicians – it concerns humanity as a whole and during the existence of the WHO also

Figure 1 The different domains, included in the international classification of functioning, disability and health.

philosophers have thought about health. Some influential views should be mentioned.

In 1975, Christopher Boorse presented his Bio-Statistical Theory (BST) (Boorse, 1975, 1977), theorizing that 'health' is a state within a range of species typical normal functioning and thresholds in the organism; consequently disease is abnormal functioning. Health is thus the absence of disease, with a strict demarcation. Normal functions can empirically and statistically be discovered by the natural sciences and are thus objective and value-free, according to Boorse. The need is to develop enough and appropriate reference classes, connected to functions. Despite diverse criticism, the appeal to reference classes is commonly accepted in health care and the theory reached the status of background theory of health and medicine (Venkatapuram, 2013).

Out of discontentment with the prevailing view of health as the absence of disease, the Swedish philosopher Lennart Nordenfelt published in 1987 (revised in 1995) his theory of 'health as the ability to achieve vital goals.' Nordenfelt described a person's vital goal as "a state of affairs that is such that it is a necessary condition for the person's minimal happiness in the long run." The stipulation 'in the long run' is aimed at avoiding the definition of health to be centered on immediate pleasure and instead, be more in line with long-term happiness, thriving, or flourishing such as Aristotle's *eudaimonia*. More recently (1995), he rephrased the definition of vital goals as "a state of affairs which is either a component of or otherwise necessary for the person's living a minimally decent life. This includes more than survival" (Nordenfelt, 2001; Venkatapuram, 2013).

In 2013, Venkatapuram proposed a modification of Nordenfelt's conception of health (Venkatapuram, 2013). He criticizes Nordenfelt's definition in that it conceptualizes vital goals as social, cultural and ethically relative and, thus, subjective and not normative; in addition, Nordenfelt does not specify a set of vital goals. Venkatapuram aims to describe a human species-wide conception of basic vital goals or 'central human capabilities and functionings,' as inspired by the capabilities approach of Martha Nussbaum, which sets a norm.

Venkatapuram reasons that 'health is a person's ability to achieve or exercise a cluster of basic human activities.' He refers to Nussbaum's 10 capabilities, which consist in a life worthy of human dignity: (1) being able to live a normal length of life span; (2) having good health; (3) maintain bodily integrity; (4) being able to use senses, imagination, and think; (5) having emotions and emotional attachments; (6) possess practical reason to form a conception of the good; (7) have social affiliations that are meaningful and respectful; (8) express concern for other species; (9) able to play; and (10) have control over one's material and political environment.

Venkatapuram stresses that these 10 capabilities, as moral entitlements emanating from a person's human dignity, become the source of political principles for a liberal pluralistic society; ensuring that each member achieves a threshold level of these 10 central capabilities become primary political goals. He expects different societies to define thresholds levels of each capability depending on their history and resources, and thus defining health as a minimal conception of human well-being (Venkatapuram, 2013).

A clear ethical statement is being made, which in its intention is similar to the ideals of the WHO. It is remarkable that a philosophy such as the one by Boorse reaches the medical establishment, whereas the philosophies of Nordenfelt and Venkatapuram do not cross the apparent gap between philosophy and medicine. Or are new developments promising for more exchange and integration?

More Health Concepts Outside the WHO in the Twentieth and Twenty-First Century

In the twentieth and twenty-first centuries also nonphilosophical professionals outside the WHO thought about the definition of health, some of whom are mentioned here.

In 1941 Henry Sigerist, a Swiss born American medical historian, analyzing the relevance of health for human welfare, stated that "A healthy individual is a man who is well balanced bodily and mentally, and well-adjusted to his physical and social environment. He is in full control of his physical and mental faculties, can adapt to environmental changes, so long as they do not exceed normal limits, and contributes to the welfare of society according to his ability. Health therefore is not simply the absence of disease; it is something positive, a joyful attitude towards life, and a cheerful acceptance of the responsibilities that life puts upon the individual" (Sigerist, 1941).

René Dubos, a French-born American microbiologist and humanist (well known by his 'Think global, act local') stated in 1968 that in his view "Health is a *modus vivendi* enabling imperfect men to achieve a rewarding and not too painful existence while they cope with an imperfect world… Health and vigour can be achieved in the absence of modern sanitation and without the help of Western medicine. Man has in his nature the potentiality to reach a high level of physical and mental wellbeing without nutritional abundance or physical comfort" (Dubos, 1968).

Ivan Illich, Austrian philosopher, Roman Catholic priest and critic of the institutions of contemporary Western culture, described health in 1975 as "the ability to adapt to a changing environment, to growing up and to aging, to healing when damaged, to suffering and to the peaceful expectation of death. Health embraces the future as well, and therefore includes anguish and the inner resources to live with it" (Illich, 1975).

Stokes, Noren, and Shindell described in 1982 health as "A state characterized by anatomical, physiological, and psychological integrity; an ability to perform personally valued family, work, and community roles; an ability to deal with physical, biological, and psychological stress; a feeling of well-being; and freedom from the risk of disease and untimely death" (Stokes et al., 1982).

In 1995 Last described health as "A state of equilibrium between humans and the physical, biological, and social environment, compatible with full functional activity" (Last, 1997).

In 1996, Tarlov analyzed the definitions of health of the past half century and concluded that there is a remarkable consistency of three conceptual components, being:

1. The capacity to perform (relative to potential).
2. The achievement of individual fulfillment; the pursuit of values, tasks, needs, aspirations, and potential.
3. In a social environment, good health provides the potential to negotiate demands of the social environment.

Salutogenesis

In addition to these definitions of health, the American-Israeli medical sociologist Aaron Antonovsky introduced in 1979 a new term on health, which he called salutogenesis (Antonovsky, 1979), i.e., the study of generating health, as opposed to pathogenesis, the study of diseases. Antonovsky found during his qualitative studies in Israel that a certain group of women, who had survived concentration camps, did not have negative health outcomes in response to their experiences and could manage stress and stay well. Apparently, some people achieve health despite their exposure to potentially disabling stress factors. Antonovsky studied the characteristics of these resilient people and found three personality traits, which in combination he called the Sense of Coherence (SOC).

SOC consists of comprehensibility, manageability, and meaningfulness. Antonovsky described meaningfulness to be the strongest factor. The importance of meaningfulness is in concordance with the findings of psychiatrist Viktor Frankl, based on his own observations among survivors of concentration camps (Frankl, 2006).

SOC reflects two of the three previously described components in Tarlov's analysis of definitions of health: The component of capacity to perform reflects manageability, whereas the achievement of individual fulfillment reflects meaningfulness. Where Antonovsky adds comprehensibility, Tarlov describes the importance of the social environment.

Antonovsky rejects the view of health and disease as sheer opposites; rather he describes the two as extremes on a continuum and stresses the possibilities to strengthen SOC, in order to enhance health. His views are further elaborated, among others, by Lindström and Eriksson (2010).

Increasing Criticism of the WHO Definition of Health in the Twenty-First Century

In 2008, Alex Jadad from Canada initiated a global conversation using a Web-based discussion forum (blog) for which he invited participants in the British Medical Journal (Jadad, 2008). This blog was like a reenactment of the discussion of 60 years ago, which led to the WHO definition, with the major difference of using the power of social media. Shortly thereafter, an editorial published in The Lancet was entitled 'What is health? The ability to adapt' (Lancet, 2009).

At that time in the Netherlands also the urgency was felt for redefining health in a more dynamic and operational way. At the end of 2009, a 2-day international expert conference was organized about 'health.' First limitations of the WHO definition were discussed and summarized as follows: (1) the absoluteness of the word 'complete,' which is utopian and stimulates medicalization; (2) the present demography of diseases, which shows no longer infectious, but mainly chronic diseases; and (3) the difficulty with operationalization, as 'complete' is not measurable. There was broad support for moving from the present static formulation of the WHO definition of health, toward a more dynamic description based on resilience and the human capacity to cope and to maintain and restore one's integrity, equilibrium, and sense of well-being.

Participants questioned whether a new formulation should be called a definition, because this implies set boundaries and trying to arrive at a precise meaning. They preferred the definition should be replaced by a concept or conceptual framework of health. A general concept, according to sociologist Blumer, represents the characterization of a generally agreed direction in which to look, as a reference. But operational definitions are also needed for practical life, such as for measurement purposes. The preferred description for a dynamic general concept was "Health as the ability to adapt and to self-manage, in the face of social, physical, and emotional challenges." This was published in the British Medical Journal (Huber et al., 2011).

In 2012–13, this general concept was further elaborated by Huber into the broad operational concept of 'positive health,' integrating objective medical and functional facts on the one hand, and SOC and meaningfulness on the other hand, thus approaching the ideals of Nordenfelt and Venkatapuram, and presenting optional concepts for 'personal factors' in the ICF. At present, (2014) a scientific publication is in preparation.

Health Economics

Abstract

Advancing medical and pharmaceutical technology has allowed us to lengthen human life spans and reduce suffering, but has also increased the health sector's use of scarce economic resources. Health economics studies the evaluation techniques and institutional arrangements that can be employed to promote efficient use of health resources and to control aggregate health care costs, as well as the social policy objective of guaranteeing that sick people have access to needed health care regardless of ability to pay.

Since the turn of the century, health care has continued to take up an increasing share of total economic resources in most countries in the world. In 1997, health care spending as a share of GDP fell in the range 6.7–13.6% for the G7 countries; by 2010, the range was 9.5–17.6%. The health economics literature has expanded apace. In 2011–12 alone, just over 10 years after the appearance of the first two-volume handbook in the field (Culyer and Newhouse, 2000), three new major survey works were published: Glied and Smith, 2011; Danzon and Nicholson, 2011; Pauly et al., 2012. Readers looking for recent references to any of the topics discussed in this article should look to these volumes in the first instance.

Health care remains one of the economic sectors in which views on the proper role of government intervention, as opposed to reliance on markets and competition, continue to be hotly debated. In some European countries, government has assumed responsibility for both the funding and production of health services; in others, funding is through government plans but production of services is mostly by private agents, while in the U.S. and a few other countries private insurance plays a large role on the funding side as well.

Much of the early literature in health economics focused on the reasons why unregulated private markets are unlikely to perform well in health care, including uncertainty and imperfect information. The demand for health services is state-contingent (most health services are demanded only when people have fallen ill), and while markets for private health insurance offer consumers an opportunity to protect themselves against the financial risk of costly health care, they accomplish this only imperfectly. In his classic article which some characterize as the origin of health economics, Arrow (1963) argues that inadequate medical knowledge and imperfect state-contingent markets put consumers in a very weak position relative to providers when they need to buy health services. As medical and pharmaceutical technology has advanced and more and more resources have been devoted to health care, economic analysis has contributed to the design of regulatory approaches to deal with this problem, and has interacted with the development of new institutional arrangements in private health care and insurance markets that have evolved as a response to it.

Insurance Protection versus Moral Hazard Effects

Under ideal conditions, efficient health insurance would consist of state-contingent lump-sum payments that would depend only on the nature of the consumer's health problem (Goddeeris, 1984b). In practice, however, it is not possible to write insurance contracts that cover all possible health problems, so benefits under conventional insurance contracts typically are specified instead as a share of the cost of the health services that the insured has used. Implicitly, such contracts therefore act as a subsidy on ill consumers' utilization of health services. As with other subsidies, this tends to make them use more than the economically efficient quantity (Pauly, 1968). This effect (referred to in the literature as 'moral hazard') implies some degree of waste in the conventional microeconomic sense, in an amount that is larger the higher is the share of cost that is covered by the insurer. The resulting trade-off between the objectives of more complete insurance coverage and avoidance of overutilization of health services has been a central topic in much of the health economics literature, beginning with Zeckhauser (1970) and in the multimillion dollar-controlled trial of differing degrees of insurance carried out by the Rand Corporation in the early 1970s (Newhouse and The Insurance Experiment Group, 1993). While the issue of patient cost-sharing ('user fees') remains controversial, the results of the Rand study supported the idea that some degree of patient cost-sharing could lead to substantial payoffs in the form of reduced overutilization of health services. Although there are exceptions in which patients pay nothing out of pocket for hospital and physician services (the U.K. National Health Service (U.K. NHS), Canada's provincial insurance plans), most private and government insurance plans today require patients to pay at least a share of the cost, subject to an annual maximum of some kind.

An approach to the moral hazard problem that has become popular in places like Singapore and China, as well as in the U.S., is that of Medical Savings Accounts (MSAs). When an insurance plan includes MSAs, enrolees must, in addition to paying the regular insurance premium, also contribute an amount to an individual account (the MSA), the balance in which they can only use to pay for their own health services in the future. In the U.S., the popularity of MSAs is due largely to the fact that contributions to MSAs are considered a nontaxable

benefit, so designating part of employees' compensation as MSA contributions reduces the income tax they must pay. The rationale for compulsory MSA contributions in other places (such as Singapore) is less easy to understand, since their only effect is to restrict the way citizens can use some of their income. However, the growing evidence from behavioral economics that individuals do not appear to make rational decisions in the face of risk and uncertainty can perhaps also be used to justify the gentle 'nudging' that is inherent in compulsory MSA contributions (Thaler and Sunstein, 2009).

Information Asymmetry, Agency, and Supplier-Induced Demand (SID)

Imperfect information on the part of insurance plans regarding the exact nature and severity of the consumers' health problems is the reason why health insurance typically pays all or part of actual health care costs, rather than lump-sum indemnities that depend on the consumers' diagnoses. But imperfect information is also a problem for patients. Sick individuals often do not know what is wrong with them, or to what extent their pain and suffering will be alleviated by different treatment approaches or drugs. Although patients today are becoming more adept at finding information about their treatment options, they still have to rely to a large extent on the advice of their doctors in deciding what services to buy. Much of the literature in health economics has focused on this asymmetry of information between doctors and patients: Coupled with the fact that it is difficult for sick people who need care urgently to compare the terms offered by competing sellers, consumers are in a weak bargaining position relative to providers in health services markets.

If doctors can influence patients' demand for their services through the advice they provide, as suggested in the literature on SID, and competition among providers is weak, the result may be both high prices and larger-than-efficient volumes of services in markets where doctors can set their own fees. The empirical evidence on the extent to which SID exists remains fragmentary and ambiguous. However, markets of this kind have become much less common over time. Levels of medical fees in most countries with government funding of health care are not market-determined but regulated or negotiated between governments and provider groups. In the U.S., they are increasingly determined in advance of treatment under contracts between providers and insurance plans who obviously have more bargaining power than individual patients. Moreover, other methods of paying providers than fee for service are becoming more common; often these alternative payment methods are structured in such a way that providers have less incentive to supply large volumes of services. These trends are consistent with the suggestion that SID is a significant problem under the conventional market forms.

As the focus has shifted from demand-side incentives (patient cost-sharing) to those that are inherent in the methods used to compensate providers (supply-side incentives), health economics has drawn on agency theory, which analyzes efficient contracts in situations where an agent with better information (in this case, the doctor) is paid to make decisions that affect the welfare of a principal (the patient) with less information. An early application of agency theory related to compensation of corporate managers; in that case the principals are the shareholders, who have less information than the managers who act as their agents. In health care, however, a key feature of the principal–agency relationship is the fact that most of the costs are paid by third parties, so that the doctors' decisions affect not only the well-being of the patients, but also of the collective that bears most of the cost (taxpayers, members of private insurance plans). To be efficient, the contracts under which the agents provide health care must give them incentives to take account both of the interests of the individual patients, and the costs borne by the collective (Blomqvist, 1991).

Compensation methods that imply enhanced incentives on providers to take cost into account include capitation in primary care (the backbone of the U.K. NHS), and episode-based payments (such as those based on Diagnosis-Related Groups (DRG)) for hospitals. Both are examples of *prospective* funding models, meaning that the payment is fixed in advance of treatment and does not depend on what volume of services the patient actually received. Under capitation (which is often combined with partial fee for service in 'blended' systems), primary care providers agree to supply services as needed for all patients on their roster, in return for a fixed monthly amount per patient. In the DRG model (which originally was developed for the U.S. Medicare plan, but now is used in many countries), the principle is that a hospital's revenue from treating given patients will depend only on the classification of their health problems, not on their length of stay or what drugs and services were actually used in treating them.

Prospective funding methods have been used not only in government plans, but also by private insurers in the U.S., in conjunction with expanded use of 'selective contracting and patient steering.' In plans that use this approach, the insured are only fully covered if they get their care from providers who have signed a contract in which they agree to be compensated for their services according to terms set by the plan, and often also to abide by restrictions in the way they will treat the plan's patients. For example, in some managed-care plans, the participating doctors have to agree to choose prescription drugs from a formulary provided by the plan, or to a second opinion before a patient can receive major elective surgery. Under selective contracting, fees and other terms according to which services are supplied are no longer determined through transactions between providers and individual patients at the point of service; instead, insurance plans negotiate the terms in advance on behalf of their insured clients. The trend toward more use of selective contracting has strengthened the market power on the buyers' side in the markets for health services and drugs, and made them more competitive in comparison with the earlier model in which the buyers were the individual patients.

Private Health Insurance: Competition, Cream Skimming, and Adverse Selection

Even though government has taken over most of the responsibility for pooling the financial risk associated with health care costs in almost all advanced countries other than

the U.S. and a few others, theoretical and empirical research on private health insurance markets continues to be a prominent part of the health economics literature. This research is motivated in part by the importance of private health insurance in the U.S. system, but also by the fact that private insurance continues to play a significant role in several other countries, as provider of supplementary coverage for items excluded from government plans (such as outpatient pharmaceuticals and dental care), or complementary coverage when the public plan contains deductibles or patient cost-sharing (as in France, or in the basic U.S. Medicare plan for retirees).

An active line of research, on risk adjustment, relates to attempts in some countries (especially the Netherlands) to allow private insurers a more prominent role in government-organized universal social insurance systems in a way that is both efficient and consistent with the equity objective. In the absence of regulation, competition among private insurance plans will cause them to charge higher premiums, or deny coverage, to individuals who can be predicted to have high expected health care costs, based on factors such as their own or their families' illness history. In order to create more equitable access to insurance, regulators can simply prohibit premium discrimination and require plans to cover everyone who is willing to pay the quoted premium. However, the theoretical and empirical literature on risk selection shows that there are ways in which insurers can design their plans so as to make them more attractive to low-risk individuals ('cream skimming'), undermining the equity objective to some extent. In response, regulators in the Netherlands and elsewhere have tried to reduce insurers' incentive to engage in risk selection by paying a risk-adjusted premium subsidy for individuals with high expected expenditure, and by restricting insurers' ability to cream-skim by limiting the extent to which they can vary the content of their coverage. Every plan must also accept any applicant willing to pay its net-of-subsidy premium (which must be the same for everyone).

Much of the early literature on private health insurance focused on the case where the information about factors leading to differences in expected costs was private (known to the buyers) and not readily observable by the insurers. As Rothschild and Stiglitz showed in their classic article on adverse selection (1976), competitive insurance markets could then break down or lead to inefficient outcomes. A somewhat surprising prediction of their analysis was that plans with generous benefits would tend to survive in a competitive market, though they would be very expensive and used only by individuals whose risk of loss was high. In the context of health insurance, the empirical evidence suggests that another consequence may be 'death spirals' under which plans with generous benefits will become so expensive that they will disappear, leading to outcomes in which surviving plans will offer only limited benefits (Cutler and Reber, 1998). The problem of adverse selection can be at least partially overcome when health insurance is in the form of a common plan that is purchased by a group of individuals who are related in some way that is independent of their expected health care costs, for example, all employees in a firm; the fact that most private health insurance in the U.S. is through employment is partly a reflection of this (Diamond, 1992).

The Industrial Organization of the Health Insurance and Health Services Industries

Selective contracting and patient steering is a means by which insurance plans can take a more active role on the buying side in the markets for health services, creating a better balance in market power between buyers and sellers. But closer integration between insurers and producers of health services can also be interpreted as a model for supplying these services that is more like the way they would be supplied in an idealized model of state-contingent contracts.

Considerable attention has been paid in the literature to Health Maintenance Organizations (HMOs), a type of firm that was considered a promising model in the U.S. health care industry in the 1970s and 1980s (Luft, 1981). In their simplest form, HMOs were insurance plans whose enrolees paid a fixed monthly premium, in return for being entitled to health services and drugs as needed, but only in hospitals owned by the HMO, and from doctors who were its salaried employees. Because the doctors were paid by salary, and the hospitals' revenues did not directly depend on the services they supplied, they had no direct incentive to supply large volumes of services. Moreover, because HMOs were responsible for the full range of health services (primary care, services of specialists and hospitals) and drugs, they could ask their providers to follow rules that would combine these inputs efficiently. Empirical evidence in the Rand study suggested that HMOs could supply care to given populations at lower cost than under the conventional model, with similar health outcomes on average (Newhouse and The Insurance Experiment Group, 1993). The fact that the U.K. health care system seems to be able to provide good care to its population at a low cost relative to others is consistent with this evidence, since the U.K. NHS can be loosely interpreted as a nationwide HMO.

HMOs and similar managed-care plans increased their share of the U.S. health insurance market to a considerable extent in the 1980s and early 1990s, and health economists like Enthoven envisaged reforms that would create an efficient system of universal insurance coverage through one of many competing plans (Enthoven, 1993). However, the 1993 reform proposals of the first Clinton administration which drew on these ideas met with vigorous opposition, and in the second half of the 1990s, there was what has been described as a 'backlash' against managed care (Havighurst, 2002). While the principle of selective contracting has survived, plans with fewer restrictions on providers and less integration between the different kinds of health services now dominate the market. In the Obamacare legislation, there are incentives encouraging different providers who treat patients under the Medicare plan to form Accountable Care Organizations for the purpose of saving resources by integrating care more closely. These provisions can be interpreted as a sign that integration of care remains an unresolved issue in much of the U.S. system (McClellan et al., 2010).

Enthoven's ideas of 'managed competition' have also been an important influence on the process of health financing reform that has been underway in the Netherlands over several decades (van de Ven and Schut, 2008). Under the legislation governing the system, the competing insurance plans from which citizens can choose are allowed to engage in selective

contracting and patient steering, although so far they have only done so to a limited extent.

Health as Capital; Communicable Disease

Part of the work in health economics has been concerned with quantifying the concept of health. In the model analyzed by Grossman (1972), health is interpreted as a form of capital. Each person is born with a certain quantity, and can build up his or her health capital by using health services produced by others, by eating well, exercising, and so on. But health capital is also subject to depreciation, as people fall ill and grow old. Health capital yields benefits in the form of a flow of healthy time which is both valuable in itself (the consumption motive for investing in health), and because it can be used to earn an income through working (the investment motive).

Empirical work on the production of health capital obviously is difficult, because health can only be imperfectly observed and measured. Nevertheless, research inspired by Grossman's analysis has yielded important insights and evidence. In particular, it has shown that childhood health, and the health services used to improve it, including prenatal care, are important predictors of adult health and well-being (Currie, 2009). It has also focused on the long-term benefits of factors such as exercise and weight control, as well as on the relation between addiction to tobacco and alcohol and health. The theory of 'rational addiction' proposed by Becker and Murphy (1988) is similar to Grossman's analysis in that both seek to reconcile the evidence on the long-term consequences of behaviors that influence health with the hypothesis of rationality in human decision making. However, the evidence from behavioral economics is casting more doubt on the helpfulness of this hypothesis in contexts that involve long time horizons and small risks of major adverse outcomes (Rabin and Thaler, 2001). Both these features are characteristic of many decisions that affect health in the long run.

In the analysis of population health, there is a critical distinction between communicable and noncommunicable diseases, with the former being much more prevalent in poor countries while the latter now dominate in rich countries. In the early health economics literature, the focus was implicitly on noncommunicable diseases and on decisions by individuals that only affect their own health. For communicable diseases, there are significant spillover effects as actions (or lack of actions) by individuals influence the health risks of others. In epidemiological models of communicable diseases, these actions have typically been taken as given. Since the 1990s, however, there is a branch of the literature that draws on both epidemiology and economics and looks at how economic incentives can influence individual decisions that affect the spread of contagious diseases (Kremer, 1996). This research has partly been motivated by the spread of HIV/AIDS, but also by the increasing attention being paid to health care and health policy in developing countries. Analysis that combines the modeling of individual incentives and spillover effects will also be relevant as more resources are devoted to the growing problem of infections that become resistant to existing drugs.

Valuing Health

Government decision makers are often called upon to evaluate projects or regulations that affect safety, for example, in the transportation sector, leading to the question whether there is a meaningful way to estimate the value of saving human lives. Following the work of Schelling (1968) and others, it is widely accepted that it is reasonable to use estimates of the value of saving a 'statistical life' (that is, the life of a person whose identity is not known in advance) on the basis of evidence regarding how much people are willing to pay for reducing the risk that they will die. Such evidence can be derived from contingent valuation (answers to hypothetical questions), or from revealed preference, for example, based on observed wage differentials between risky and safe jobs (Viscusi, 1993). Estimated values of reducing mortality are obviously relevant to health economics, since much of what is spent on health care goes toward drugs and interventions that increase the chances of survival among patients with different kinds of illness. Murphy and Topel (2006) argue that conventional GDP statistics have seriously underestimated secular growth in human welfare because they fail to account for the value of increased life expectancy, which has occurred at least partly in response to the development of new drugs and medical technology.

Death, however, is only the most extreme form of ill health; the main purpose of many types of health care is to improve patients' quality of life, not just to reduce the risk of death. An active branch of health economics research has concerned itself with the development of a generalized health index, quality-adjusted life expectancy, that accounts both for improvements in the quality of patients' lives and longer life expectancy. In calculating the expected number of quality-adjusted life years (QALYs) among members in a given population, a year lived with a disabling or painful health problem is counted as the equivalent of a fraction of a year lived in normal health. Much of the research in this area has been about simple methods to estimate what quality-of-life weights should be assigned to years lived with different kinds of health problems, based on patients' answers to hypothetical questions.

Cost-effectiveness evaluations of different treatment approaches or drugs that compare their costs with their ability to produce additional QALYs in given patient populations are increasingly common in the literature; the term 'cost-utility analysis' is often used to refer to this methodology. In countries where most health care is directly paid for by government, such as the U.K., certain procedures or drugs may not be approved for coverage under the public plan if their cost-effectiveness is unfavorable (the cost per incremental QALY is too high), but even in the U.S. where coverage restrictions are opposed by many who object to 'rationing' of patients' access to care, economic evaluations can play a role in establishing clinical guidelines or drug formularies that are used by many insurance plans.

Although cost-utility analysis is widely used, certain conceptual issues remain controversial, for example, whether future QALYs should be discounted, and when it is appropriate for an evaluation to include only costs to the government as opposed to costs borne by all members of society, including private individuals. Or, in calculating the costs to society of

using a new technology that reduces mortality, should one include an allowance for the fact that additional survivors will mean higher health care costs in the future, as well as more resources required for their consumption of other goods and services?

The importance of providing information and incentives to make cost-effective choices in medical care has been indirectly illustrated by studies showing large variation in practice patterns across different locations; this line of research has been particularly active in the U.S. Data on the per capita cost of medical care in similar populations (for example, U.S. retirees covered by the Medicare plan) show differences of a hundred percent or more in comparisons across major urban areas, and while they can be attributed in part to different unit prices for various services, they remain large even after correcting for this. Studies of particular procedures also show wide variation in the rates at which they are applied in comparable populations. These findings lend credence to the widely held view that large gains could be realized (either in the form of lower cost or better health outcomes on average) if practice patterns everywhere could be made to align more closely with the findings of cost-effectiveness studies.

Pharmaceuticals and Medical Technology

While other factors, such as the high labor intensity of health care production, have contributed to the increase in health care spending as a share of GDP in almost all countries, the main driver appears to have been the continuing development of new and often costly types of medical and pharmaceutical technology. The costs of developing and using the new technologies have been high, but their benefits, in the form of longer life expectancy and better quality of life have been large and, on average, have more than justified the costs (Murphy and Topel, 2006). New technology will continue to come on stream, partly driven by advances in molecular biology and research on the human genome, but several issues regarding the cost of developing and using new technology remain controversial.

Financing of global R&D is to a large extent through the patent system under which an incentive to develop new technology is provided through legal rules that give the patent owner a time-limited monopoly in the market for any products that use the patented technology. The most important health-related industry in which R&D is financed in this way is the pharmaceutical industry. Although most countries are bound by international agreements that place certain restrictions on their patent laws, national governments still retain considerable discretion with respect to the detailed rules regarding matters such as the definition of what constitutes a patentable invention, the length of the patent period, and what rules apply to competing producers (such as manufacturers of generic drugs) when the patent expires for a brand-name drug.

The application of the patent system in the pharmaceutical industry involves the same trade-off as in other sectors, between the need to create an incentive for future R&D spending, on the one hand, and the desire to quickly make new technology available to consumers at a reasonable price, on the other. However, in the market for drugs, the trade-off is complicated by the fact that they typically are paid for by third parties (public or private insurance plans), not by the consumers themselves. Prices of patented drugs in many countries therefore tend to be regulated by government, or established in bilateral negotiations between central agencies and the patent owner, with evidence from health economic evaluations playing a role. Rules with respect to drug patents have been important elements in international trade negotiations. In these negotiations, countries or jurisdictions where the large and research-intensive pharmaceutical firms are located and generate jobs and tax revenue (the U.S., the E.U., Japan) tend to push for policies that lead to high drug prices and revenue for these firms. Smaller and poorer countries that mostly use drugs that have been developed elsewhere prefer rules that shorten the period of patent protection, lower the prices of patented drugs, and allow quick entry of lower-cost generic drugs after the patents have expired.

The nature of R&D in the pharmaceutical and medical devices industries in the future may also be affected by the changing roles of insurers and of physicians as agents of both patients and third parties in many health care systems. In important early contributions, Goddeeris (1984a,b) introduced the idea that firms engaged in R&D face a choice between efforts to develop cost-saving technology (that would reduce the cost of existing treatment methods), or technology that leads to increased spending because it enables providers to effectively treat new patients with problems for which current methods do not work. His insight was that when doctors act exclusively in their role as agents for their patients, they would look relatively more favorably on the latter type of innovations, since most of the additional costs will be paid by third parties, not by the patients. As more doctors work under contracts that also give them an incentive to pay attention to the costs of the third party, the implicit bias against cost-reducing innovations will be reduced, at least to some extent.

Health Economics, Health Policy, and Equity

Mandatory social insurance programs or direct government funding of health services are crucial elements of the welfare state in many countries that strive to attain a more equal distribution of income. The correlation between health and income or social status has been known for a long time, and continues to be explored in the literature. The question to what extent low income causes ill health or the other way around (or whether both are correlated with some third factor) remains open, but the correlation persists even in systems where universal government programs has largely eliminated income as a determinant of access to health care.

Most of the literature on economic inequality concerns itself with the distribution of measures of real income, whether in a given year or over individuals' lifetime; less attention is paid to the question how inequality is reflected in different rates of consumption of specific goods and services. In health economics, however, there is a substantial literature on inequality in the utilization of health care, and whether it is correlated with income, partly reflecting the view that society should be less tolerant of inequality in health care than for other kinds of consumption (Tobin, 1970). In some countries,

for example Canada, there is widespread support for the idea that utilization of health services should be independent of income, and various policies are used to discourage purchases of health services outside of the government plans even by people with high income who are willing to pay for them. An important question for the future, especially in countries with universal coverage through government plans, will be to what extent their health financing systems will allow choice for individuals among insurance plans with different treatment strategies and hence expected costs (Havighurst, 2002). This question will become more urgent as medical and pharmaceutical technology continues to progress and introduce a wide range of new drugs and methods that can be used to improve expected health outcomes, but often at very high cost. The aging of the population in many countries is relevant to this issue, since a large proportion of health care costs typically are incurred by older patients who are nearing the end of their lives. Rising government expenditure to pay for the health care costs of the elderly therefore contribute in a major way to the increasing burden that the relatively small younger generations of working-age taxpayers face in countries where the proportion of retirees will rise over the next several decades.

Health care and health insurance are not internationally traded to any significant extent, so there is little competition among providers and insurance systems across countries. While much of the research in health economics remains country-specific, the literature comparing health care systems and policies in different countries has become increasingly important over time, especially in the twenty-first century. A country whose health policy is attracting great interest is China, where it is a critical element in the regime's efforts to reduce inequality, and health care reform is accorded a high priority because the current market-oriented model compares unfavorably, from the viewpoint of equity, with the one that existed before the 1980s when the experiment with less centralized economic management began (Qian and Blomqvist, 2014).

Abstract

Health promotion is any planned combination of educational, political, regulatory, and organizational supports for actions and conditions of living conducive to the health of individuals, groups, or communities. Health education is one type of health promotion intervention. Health education is a planned activity, stimulating learning through communication, to promote health behavior. In this article we give definitions and examples of health promotion, health education, and prevention. The PRECEDE-PROCEED model is explained and illustrated and the importance of systematically planning interventions is supported with evidence. Theories are the basis for evidence-based planning. We present Intervention Mapping as a protocol for developing theory- and evidence-based health promotion interventions. Appropriate theories for determinants analysis, intervention development, and anticipation of implementation are listed with practical applications.

Health Promotion, Health Education, and Prevention: Definitions and Perspectives

Definitions

Health promotion is any planned combination of educational, political, regulatory, and organizational supports for actions and conditions of living conducive to the health of individuals, groups, or communities (Green and Kreuter, 2005: pG4). Three types of prevention are the goals of health promotion: (1) primary prevention; (2) early detection and treatment; and (3) patient care and support. Alongside prevention, which is disease oriented, health promotion also aims for enhancing participation, improving living circumstances, and optimizing health; it is the process of enabling people to increase control over and improve their health focusing on the determinants of health (WHO, 1986). Different from marketing and advertising, the goals of health promotion are derived from consensus declarations about health and quality of life, by organizations such as the World Health Organization (WHO) or the United Nations.

Health education is one type of health promotion intervention. Health education is a planned activity, stimulating learning through communication, to promote health behavior. Other health promotion instruments are facilities or resources and regulation. Health education is based on voluntary change, while regulation is based on forced compliance and will only be effective in combination with control and sanctions.

In general, interventions which use a variety of health promotion instruments will be more effective. An example of this last statement is the prevention of drinking and driving. There is regulation: most countries have laws against driving under the influence of alcohol. Often there is control: drivers are stopped by the police and may be tested, although countries differ in their commitment to these control activities. There are facilities: public transport is available and, especially in the weekends and during the night, cheap taxis for adolescents. There is education: information is provided about the rules and possible sanctions, about the facilities, and about drunk driving itself, i.e., the consequences of drunk driving, but also on ways to prevent getting into that situation. The combination of control, facilities, and education is more effective than any one of these elements alone.

Health promotion as an intervention for patient care and support is usually called patient education instead of health promotion. Patient education is defined as a process of assisting people to learn health-related behaviors, so that they can incorporate those behaviors into daily life (Bastable, 2006: p. 11). Sometimes patient education supports patients who recover, for instance, after surgery. Sometimes the focus is on chronic patients, such as patients with asthma or diabetes; health promotion seeks to support disease management and self-management. Patient education also includes slowing down deterioration as well as support for people who are dying, for instance, in the case of terminal cancer. Patient education is not only directed at the patient but also at the patient's family, at health professionals, and at the environment. Health workers such as physicians and nurses are the primary providers of patient education and they need to be motivated and skilled to do so. Frequently, many different health workers are involved in the treatment of the same patient. Patient education by each of these professionals is not always attuned to the needs of the patient. This calls for the development of patient education programs that coordinate the educational activities of the different health professionals involved, for example, by developing protocols for continuity of care.

Perspectives

Current health promotion research and practice is characterized by three perspectives: an ecological approach, participation of all stakeholders, and the use of theories and evidence.

People's behavior is not only determined by personal factors but also by environmental conditions: social networks, organizations, communities, and society. We call that the ecological approach (Kok et al., 2008). The key to understanding environmental conditions is the recognition of agents in the environment, also called decision-makers or gatekeepers. At every environmental level there are agents who decide about an environmental condition. To change those conditions, we

have to understand the behavior of the agents and plan interventions to influence the agents' behavior.

Participation is another essential element in health promotion; participation of the target population, relevant environmental agents, and potential implementers of the intervention (Belansky et al., 2011). Principles of participation include: build upon community strengths, facilitate equitable decision-making in an iterative process, foster colearning among partners, local problems, and multiple determinants of health.

Careful intervention planning makes health promotion an evidence-based practice. Evidence can be found in empirical research but also in theory. Most health promotion interventions are based on theories and research in an iterative process of brainstorming, reviewing the literature, applying theories, and executing additional research (Bartholomew et al., 2011; Buunk and van Vugt, 2013). This is also a continuous process; evidence-based health promotion means that effective interventions may be adapted for implementation in other communities, again based on theories and research.

The Planning of Health Promotion

Green's PRECEDE-PROCEED Model

Health promotion is a planned activity. The best known and most often used planning model in health promotion is Green's PRECEDE-PROCEED model (Green and Kreuter, 2005). In short, Green starts with the social assessment: what is the quality of life of a certain group, community, or country, and the epidemiological assessment; is health relevant for the quality of life and if it is, what are the most serious health problems? With the epidemiological assessment, the causes of health in terms of behavior/lifestyle, genetics, and environment can be analyzed. With the educational and ecological assessment, an analysis can be made of the determinants of the relevant behaviors, in terms of predisposing, reinforcing, and enabling factors, and the variables can be selected that one wishes to influence. With intervention alignment and administrative and policy assessment, the possible usefulness of health education and other potential interventions, of facilities and regulations, can be analyzed. Health promotion interventions are developed and then implemented. Finally, evaluation is made of the process, impact, and outcome of these interventions, resulting in feedback and improvement of the interventions.

An Example of PRECEDE-PROCEED

For example, in most Western countries, the quality of life in general is high. People value health as one of the most important aspects of their quality of life, especially when it is threatened. What are the most important health problems? In terms of mortality, cardiovascular disease (CVD) and cancer fulfill this role. What are the causes of CVD and cancer? In terms of environment, these are, for instance, industrialization and unhealthy working environments. In terms of behavior and lifestyle, smoking and distorted energy balance (diet and physical activity) are major causes. Let us select smoking and, in particular, the prevention of the onset of smoking, as a relevant behavior that we might want to influence. Why do adolescents start smoking? Not because they like it and not because they do not know about the dangers. One reason is social pressure, mostly from peers, family, or mass media. In terms of predisposing factors, adolescents often do not know how to resist social pressure.

In terms of reinforcing factors, belonging to a peer group is very important for adolescents. In terms of enabling factors, cigarettes are easy to obtain and sanctions against smoking are weak. What can we do? In terms of health education, we might want to improve adolescents' self-efficacy in resisting social pressure. There are a number of techniques that help adolescents to learn how to resist pressure to smoke, for instance, through positive role modeling (see Bartholomew et al., 2011). In terms of facilities and regulation we want to develop anti-smoking policies, for instance, in schools, or through community action against vendors who sell cigarettes to adolescents under legal age. The implementation of such a health promotion program is organized in cooperation with schools, parents, and students. Finally, the effectiveness of the program is measured. In terms of process evaluation, the central question is: was the program implemented as planned and was the supposed self-efficacy improvement actually realized? In terms of impact evaluation: did fewer students in our program group start smoking than in a comparison group? It may be clear that an improvement in terms of outcomes, reduction of CVD and cancer, and quality of life, cannot be expected for several years. For some behaviors there are predictive models to estimate these improvements, often enabling cost-effectiveness analysis.

Quality of the Planning

The process of planning health promotion programs is a cumulative and iterative process. On the one hand, we need answers on earlier planning questions to decide about later phases. On the other hand, the process is not rigid but flexible and we go back and forth through the model. During the planning process we make use of existing knowledge that is systematized in theories, and which is available as empirical data. Why does it have to be so complex? Certainly not because health promoters admire complicated models, but because careful planning is essential if we strive for effect.

Theory-Based Interventions

A very important early study in this respect is a meta-analysis by Mullen et al. (1985) on 70 patient education studies that were methodologically sound and which included knowledge and compliance or adherence as effect variables. Several diseases and several types of interventions were represented. Mullen et al. estimated the quality of the interventions using six criteria that they derived from literature and that can also be seen as guidelines for intervention development:

1. Consonance: the degree of fit between the program and the program objectives.
2. Relevance: the tailoring of the program to knowledge, beliefs, circumstances, and prior experiences of the learner, as assessed by pilot testing or other means.

3. Individualization: the provision of opportunities for learners to have personal questions answered or instructions paced according to their individual progress.
4. Feedback: information given to the learner regarding the extent to which learning is being accomplished (e.g., blood pressure reading).
5. Reinforcement: any component of the intervention that is designed to reward the behavior (other than feedback) after the behavior has been enacted (e.g., social support).
6. Facilitation: the provision of means for the learner to take action and/or means to reduce barriers to action (e.g., subsidies).

Mullen et al. show that the best predictor of success was the rating score for the quality of the educational intervention. The choice for a specific educational technique was not related to effectiveness, again demonstrating that there is no such thing as a 'magic bullet.' Thus, the effectiveness of a health promotion intervention is determined by the quality of the planning process. In the six criteria that Mullen et al. used, we recognize different concepts from Green's planning model: the choice of relevant behavioral objectives, tailoring to determinants of behavior, learning (health education), reinforcement, support, and facilitation (health promotion). There are also some additional concepts that have not been described in the PRECEDE-PROCEED model, but which are selected from behavioral science theories, especially Social Cognitive Theory (McAlister et al., 2008).

Reviews and Meta-Analyses

Recent reviews and meta-analyses also demonstrate a positive relationship between the use of theory-based intervention methods and the effectiveness of the intervention (Albarracín et al., 2005; de Bruin et al., 2009; Fisher et al., 2002; Peters et al., 2009; van Achterberg et al., 2010). In these reviews, theory-based methods were coded from intervention descriptions, after which the authors show an association between the number of theory-based methods used and the effectiveness of interventions. Even while it was impossible to evaluate the appropriateness of the way the methods were used (which is crucial in the correct application of methods, see Peters et al., ahead-of-print), still the conclusion is that the quality of the planning process is a key for intervention success.

Intervention Mapping

Intervention Mapping is a protocol for developing theory- and evidence-based health promotion programs (Bartholomew et al., 2011). It describes the process of health promotion program planning in six steps: (1) the needs assessment based on the PRECEDE-PROCEED model; (2) the definition of performance and change objectives based upon scientific analyses of health problems and problem causing factors; (3) the selection of theory-based intervention methods and practical applications to change (determinants of) health-related behavior; (4) the production of program components, design and production; (5) the anticipation of program adoption, implementation and sustainability; and (6) the anticipation of process and effective evaluation. Intervention Mapping recognizes the earlier mentioned perspectives: an ecological approach, participation of all stakeholders, and the use of theories and evidence. Although Intervention Mapping is presented as a series of steps, Bartholomew et al. (2011) see the planning process as iterative rather than linear. Program planners move back and forth between tasks and steps. The process is also cumulative: each step is based on previous steps, and inattention to a particular step may lead to mistakes and inadequate decisions.

An Example: Long Live Love

An example of the use of Intervention Mapping in program development is the Long Live Love HIV/STI-prevention program for Dutch adolescents (Schaalma and Kok, 2011):

1. Needs assessment: In the needs assessment, the desired behavioral and environmental outcomes are identified. HIV is a serious health problem and young people today face increased risk of infection. In addition health promotion programs are most effective when the population has not yet formed risky behavior pattern and habits. The most relevant outcome related to HIV/STI prevention for adolescence is a behavioral outcome: condom use.
2. Performance and change objectives: Performance objectives are the specific behaviors that we want the target group (or the environmental agents) to 'do,' as a result of the program. For example, in the case of HIV prevention; buy condoms; have them with you; negotiate with your partner; use them correctly; and keep using them. The next task is to identify the determinants of the performance objectives: factors that have been shown to be associated with the behavior. Change objectives are the combination of target group, performance objectives, and determinants: they describe what the target individual or agent has to learn (determinant change) in order to do the performance objective. One change objective for an HIV-prevention program in schools would be: "adolescents (target population) express their confidence (determinant) in successfully negotiating with the partner about condom use (performance objective)."
3. A theoretical method is a general technique or process derived from theory and/or research, for influencing changes in the determinants of behavior; applications are specific techniques for practical use of a method in ways that fit the target group and the setting. For instance, one method for self-efficacy improvement (for negotiating) could be modeling, and the application for adolescents in school could be peer modeling by video. Every health promotion intervention exists of many applications of many methods. Bartholomew et al. (2011) give a systematic description of methods for each determinant and each level. In the literature there is an increasing interest in systematic descriptions of methods, or behavior change techniques at the individual level (Abraham and Michie, 2008) as well as the environmental levels (Khan et al., 2009). However, there is more to methods than just definitions if the planner wants to select appropriate methods for an intervention (Peters et al., ahead-of-print). An important task in this step is to identify the conditions or parameters that limit the

effectiveness of theoretical models, such as identification, observability, and reinforcement as necessary conditions for the effectiveness of learning by modeling. Bartholomew et al. (2011) also provide the parameters for use for a large number of methods.

4. The actual designing of the program involves organizing the applications into a deliverable program and producing and pilot testing the materials. In the example of the 'Long Live Love' HIV-prevention in schools, the program comprised five lessons, an interactive video, a brochure for students, and a workbook for teachers.
5. The first activity to anticipate implementation, actually at the start of intervention development, is the development of a linkage system, linking program developers with program users. Then, a specific intervention is developed that aims to promote adoption and implementation of the program by the intended program users, analyzing performance and change objectives, and specifying methods and applications.
6. Finally, Intervention Mapping step 6 anticipates process and effects evaluation. Again, this is relevant from the start. For instance, "adolescents express their confidence in successfully negotiating with the partner about condom use" is an objective, but is also a measure of that objective, that can be asked in pre- and postinterviews with experimental and control group subjects.

Using Theories in Health Promotion: Determinants

At different phases in the planning process different theories will be most relevant (Glanz et al., 2008; Simons-Morton et al., 2012). The first phases rely on epidemiological theories; the later phases, when the intervention is developed, rely on theories from the behavioral sciences, especially social psychology. In this and the next two paragraphs we will describe theories that can be applied in the three phases: determinants, intervention, and implementation. In the phase of looking at determinants we try to understand why people behave as they do. We distinguish ecological, social cognitive, and automatic determinants of behavior.

Ecological Determinants

People's behavior is not only determined by personal factors but also by environmental conditions: social networks, organizations, communities, and society (Kok et al., 2008). A changed, facilitating environment without barriers makes the health promoting behavior the easiest behavior. At each environmental level there are agents who decide about an environmental condition, for example: parents, managing boards, newspaper editors, legislators. Environment-oriented theories, explaining ecological determinants of behavior and suggesting methods to change those, have become more popular in health promotion, for example: systems theories, empowerment theories, Stakeholder Theory, and Agenda-Building Theory. At each ecological level there are agents who can change the system to facilitate health. Most environment-oriented theories focus on changing (the behavior of) agents; see the next section.

Social Cognitive Determinants

Current social psychological models indicate three types of social cognitive determinants of behavior (Fishbein and Ajzen, 2010: Reasoned Action Approach; Montano and Kasprzyk, 2008: Integrated Behavioral Model; McAlister et al., 2008: Social Cognitive Theory):

1. Attitude: beliefs about advantages and disadvantages of behavior resulting in an attitude about the behavior, also described as outcome expectations.
2. Social influence: beliefs about social norms (subjective norms, injunctive norms) and about behavior of others (descriptive norms, vicarious learning, modeling).
3. Self-efficacy: beliefs about perceived control, self-efficacy expectations.

In health promotion, theories that are more specific for risk behavior are also applied. They indicate four basic types of risk-related social cognitive determinants (Champion and Skinner, 2008: Health Belief Model; Ruiter et al., 2014: Protection Motivation Theory and Extended Parallel Process Model):

1. Seriousness: how serious is the consequence of the risky behavior?
2. Susceptibility or vulnerability: is that going to happen to me?

Together these two form the threat appraisal.

3. Response-efficacy: what can I do to avoid those consequences?
4. Self-efficacy: am I confident that I can do that?

Together these last two form the coping appraisal. If people see a threat, they try to control it. If the recommended action is thought to be effective and feasible, people will try to perform the recommended action: danger control. However, if the recommended action is thought to be ineffective or impossible, then the threat will result in defensive reactions, denial or avoidance coping: fear control.

Models about determinants of behavior do not imply a one-directional influence; attitudes, social influence, self-efficacy, and risk appraisals can be antecedents as well as consequences of behavior. In interventions we try to change determinants in order to change behavior, but we also use techniques that influence behavior rather directly, such as reinforcement and having people publicly commit themselves to the desired behavior. Positive experiences with behavior, in turn, may change psychosocial determinants of behavior, thus creating reciprocal determinism.

Automatic Determinants

Much of health promotion research and theory is based on the assumption that people are consciously and systematically processing information in order to construe and interpret their world and engage in action. However, recently, there has been greater focus on automatic, impulsive, or habitual behavior (Hassin et al., 2005). Habits are learned sequences of acts in response to environmental cues that become automatic: for example, taking the elevator instead of the stairs (Danner et al., 2008). However, Fishbein and Ajzen (2010: p. 53) argue that

habits are still predicted by intentions. Goal-directed behavior may start consciously but become automatic over time; for example, driving a vehicle or drinking water with meals.

Reflective behavior is the result of deliberation and conscious control; impulsive behavior is directed by learned associations with pleasure and pain; for example, consuming snack foods even when the intention is to eat more healthy (Hofmann et al., 2009: dual systems theories). While social cognitive determinants can be identified through self-reports, impulsive reactions can be measured by implicit measures; for example, the Implicit Association Test (Greenwald et al., 1998). Automatic and impulsive behaviors are often guided by external stimuli, and are more likely when the individual has reduced cognitive resources or lacks motivation to allocate resources. Impulsive behavior may also be a reason why adolescents and young adults take more risks. Research in neuroscience shows a relatively slow maturation of the cognitive control system in puberty (Steinberg, 2007).

Using Theories in Health Promotion: Interventions

Stage Models

Some current general social and health psychological models on behavior change distinguish steps, phases, or stages of change. Within those steps, a number of different specific theories can be applied. One general framework for theories on behavior change is provided by McGuire's (2001) persuasion–communication model. He describes different steps that people take, from the initial response to the message to, hopefully, a continuous change of behavior in the desired direction. Simplified, the first steps indicate successful communication, the next steps involve changes of determinants and behavior, and the last step is concerned with maintenance of that behavior change. Going through these steps, McGuire argues that the educational interventions should change with each step. The choices that have to be made about the message, the target group, the channel, and the source, will be different, or may even be conflicting, depending on the particular step that is addressed: for example, mass media may reach many people but are not adequate for self-efficacy improvement. At various steps, people may have different tendencies to process the information with either high or low elaboration likelihood, also called the central or the peripheral route (Petty et al., 2009: Elaboration Likelihood Theory). Information processing may be disturbed by lack of motivation and lack of abilities, caused by information complexity and external factors.

The Transtheoretical Model or Stages of Change Model (Prochaska et al., 2008) distinguishes stages of change within the person: precontemplation, contemplation, preparing for action, action, and maintenance or relapse. An important contribution of the stage model is the specific tailoring of health promotion efforts to groups of people in different stages. Interventions based on the model usually have different methods or applications for each stage, the so-called processes of change. There is considerable debate on the validity of the specific stages; some authors suggest that there are only two stages: motivation and action (Brug et al., 2005; see Fisher et al., 2009). A frequently used application of the theory is the motivational interviewing counseling method (Miller and Rollnick, 2012).

Learning, Goals, and Self-Management

Many theories provide possibilities for intervention methods directed at behavior change. Learning theories assume that experiences shape behavior, through classical and operant conditioning (Kazdin, 2008). Methods derived from learning theories include: conditioning, modeling, feedback, and reinforcement. Theories of information processing describe how information is perceived, stored, and retrieved (Kools, 2012a,b). Preexisting schemes may function as facilitators or barriers to information processing. Methods derived from information processing theories include chunking, advance organizers, imagery, and providing cues.

Theories about risk behavior (see 'Determinants') recognize perceived threat in relation to perceived coping (Ruiter et al., 2014). Methods derived from risk perception theories include: framing, self-affirmation, coping skills, and fear appeals (the last only under appropriate, rare conditions). Theories about social cognitive determinants, such as the Reasoned Action Approach, do not provide change methods, but identify outcome, social and control beliefs that need to be influenced in order to change the behavior (Fishbein and Ajzen, 2010). The Social Cognitive Theory (McAlister et al., 2008) suggests methods such as modeling, guided practice, and feedback.

Goal Setting Theory assumes that goal setting leads to better performance because people with goals exert themselves to a greater extent, persevere in their task, concentrate more, and more often develop applications (Latham and Locke, 2007). Goal setting is most effective when the goal is challenging but feasible. Theories of goal-directed behavior assume that people hold personal goals, which represent desired outcomes. One barrier for achieving one's goal is habitual behavior (see 'Determinants'). Change methods derived from goal theories include implementation intentions (Gollwitzer and Sheeran, 2006), cue altering, and planning coping responses.

Theories about attribution and relapse prevention suggest that people differ in making stable versus unstable attributions for successes and failures (Marlatt and Donovan, 2005). People who make stable attributions for failure are inclined to give up their change goals. Methods derived from these theories include reattribution training, relapse prevention, and planning coping responses. Self-regulation or self-management is an active, iterative process of observing oneself, making judgments based on observation, setting goals, using strategies, reacting accordingly, and revising one's strategy (Clark, 2003). Methods derived from self-regulation theories include self-monitoring, feedback, and methods to change self-efficacy and skills.

E-Health

A relatively recent development in interventions is the use of information and communication technology (ICT) in care, shortly e-health. The application of ICT started with the use of telephones and automated calls (McBride and Rimer, 1999), and by creating written messages generated by a computer

(Ruiter et al., 2006), but e-health as a method has exploded with the availability of the Internet and broadband connections. In health care, the creation of electronic patient records makes information available wherever it is needed; telemedicine applications can enter information into these records. This also enables quick support in self-management, varying from supplying immediate feedback and advice after measurement, e.g., of blood glucose, to sending text messages to remind patients to take their medicine. Also in prevention, such possibilities can facilitate the provision of quick and relevant services or messages.

Computer software has been developed that can adapt health communication to specific characteristics of respondents, for instance, tailored to specific determinants of health behaviors such as knowledge, motivation, attitudes, risk perceptions, intentions, concrete plans, perceived control, etc. Depending on answers to questionnaire items, a person might be supported in developing self-efficacy or alternatively receive information concerning the advantages and disadvantages of adopting a certain diet. The flexibility of computer-delivered messages also makes it possible to personalize messages and to adapt communication styles, e.g., providing written text or a spoken message according to the preferences and literacy of the receiver.

Effective computer tailoring makes use of determinant theories and intervention theories as described in the last paragraphs to create a diagnostic instrument, for instance, focusing on specific beliefs or matching to stages and processes of changes as described in the Transtheoretical Model. After taking this instrument, a rule base is used to compose messages consisting of relevant elements.

Tailored messages have been shown to be more effective than generic messages in changing health behavior (Krebs et al., 2010), among others because they attract and keep the attention of the receiver (Ruiter et al., 2006).

Changing Environmental Conditions

An individual is embedded within social networks, organizations, community, and society; and each lower level is embedded within higher levels. Next to changing the individual, the health promoter wants to change unhealthy environments and the agents that control or influence the environment, or more precise: the determinants of those agents. These determinants are personal but also environmental. And a personal determinant of, for example, a manager is not a personal health threat, but a threat for the organization. And perceived self-efficacy is not related to changes in the manager's personal life, but confidence in bringing about organizational changes. All methods at the individual level may be used for changes at the higher environmental levels. But at those higher levels, there are more theoretical insights that may be applied.

Some theories can be applied to any environmental level: systems theories, theories of power, and empowerment theories. Systems theories are used to define and address all levels of the environment as interrelated social systems (National Cancer Institute, 2007). Methods derived from systems theories include systems change, participatory problem solving, and feedback. Power theories identify various forms of power, and agents at each level with power are able to exert their influence to make environmental changes (Turner, 2005). Methods include persuasion, coercion, community organizing, and agenda setting. Empowerment theories address the process by which community members become involved in their communities and take action to gain power and control (Minkler et al., 2008). Methods include participation, enactive mastery experiences, feedback, and modeling.

Interpersonal level theories deal with social networks and social support: family members, friends, peers, neighbors, associates, and service providers. A social network is an analytic framework for understanding relationships among members of social systems (Heaney and Israel, 2008). Social networks provide emotional, instrumental, informational, and appraisal support. Methods for change include enhancement of existing networks, use of lay health workers, participatory problem solving, and linking members to new networks.

Organizational level theories focus on the development of health promoting organizational structures and culture (Butterfoss et al., 2008; Cummings and Worley, 2014). Methods at the organizational level include sense making, participatory problem solving, organizational diagnosis and feedback, and technical assistance. Stakeholder Theory provides guidance to health promoters, working through their own organization or through the community to change an organization's policies and practices (de Bakker and den Hond, 2008), using methods such as alliances, coalitions, and social action.

Community-level theories relate to coalitions, social capital, social norms, conscientization, and community organization. A coalition is a method for influencing community and policy environmental outcomes (Butterfoss and Kegler, 2009). Social capital is defined as the processes and conditions among people and organizations that lead to accomplishing a goal of mutual social benefit (Green and Kreuter, 2005). Social capital is associated with good health. Community members and opinion leaders at various levels demonstrate and support health promoting behavior, resulting in health promoting social norms (Kelly, 2004). Methods to influence social norms include entertainment education and behavioral journalism. Conscientization, or critical consciousness, links individual- and community-level empowerment and is a key method for strength-based community organization (Wallerstein et al., 2004). Methods include reflection-action-reflection and nonjudgmental small-group discussion. Community organization theories distinguish three types of community organization (Minkler et al., 2008; Rothman, 2004). Locality development raises consciousness about the underlying causes of problems and identifies strategies for action. Social planning uses information derived from empirical research. Social action is based on coercive change and seeks to redress imbalances of power. Methods to promote community capacity include participation, using lay health workers, and media advocacy. The community, in turn, may use methods such as participatory problem solving, forming coalitions, and advocacy to promote a healthy environment.

Theories of public policy identify policy makers as the agents for the environmental outcomes of health promoting policies (Clavier and de Leeuw, 2013). These agents enact

legislation, regulation, and policy (Longest, 2006). Agenda-Building Theory and Multiple Streams Theory both describe agenda setting as the process of moving an issue to a higher agenda status (Kingdon, 2003). In policy advocacy, timing is essential; and opportunity knocks for those advocates who are well prepared at the moment that the 'windows' between politics, problems, and policies are open. Methods at the societal level include policy advocacy, agenda setting, and timing for policy windows. While quite difficult to study, there are convincing examples of scientific research and evaluation at environmental levels, including the policy level, that result in better informed policy and practice (see: www.CampbellCollaboration.org; Chen, 2014).

These environmental changes relate to the definition of settings for health promotion that the WHO has formulated in the Ottawa Charter, focusing on the contexts in which people live, work, learn, and relax (WHO, 1986). The setting approach emphasizes the potentials for health in daily life rather than disease, using natural environments like the workplace, the school, the hospital, the community, and the city. Since settings are mutually embedded (a school in a neighborhood in a city) this approach adopts an ecological view.

Using Theories in Health Promotion: Implementation

Development of an educational intervention includes making plans for program implementation, because no intervention can have any effect when it is not implemented. Implementation ensures that the intervention reaches the intended population. The adoption of innovations is a systematic process, following the pattern of diffusion of innovation (Oldenburg and Glanz, 2008; Rogers, 2003). Implementers can be distinguished by adopter category, such as innovators, early adopters, early majority, late majority, and laggards. Relevant performance objectives are adoption, implementation, and sustainability of the intervention. Especially sustainability may require an organizational change in the implementing organization (Durlak and DuPre, 2008). A number of characteristics of the intervention are related to faster adoption: compatibility, relative advantage, flexibility, observability, 'trialability' (can the innovation be tried before making a decision?), low risk, reversibility, and low complexity.

Currently, diffusion researchers stress the importance of carefully developing the linkage between the change agent system and the target group system (Fleuren et al., 2004; Oldenburg and Glanz, 2008). In, for example, smoking prevention in schools, it is important to involve teachers and students in the development of the program, as well as principals and parents. In, for example, cooperation among different health professionals to achieve continuity of care, it is important to involve all those groups in the development of the protocol.

Epilogue: Planned Health Promotion

Health promotion is any planned combination of educational, political, regulatory, and organizational supports for actions and conditions of living conducive to the health of individuals, groups, or communities. Health education is a planned activity, stimulating learning through communication in order to promote health behavior.

Health promotion planning involves a series of phases where quality of life, health problems, health behavior, determinants of behavior, and possible interventions are successively analyzed, followed by the development and implementation of the intervention and evaluation of the process, impact, and outcome. Careful planning is important, since quality of planning has been shown to determine effectiveness of the intervention.

Intervention Mapping provides a helpful protocol for theory- and evidence-based health promotion planning. A wide range of theories from the behavioral sciences may contribute fruitfully to the analysis of determinants and to the development and implementation of health promotion interventions.

Abstract

Health geography emerged from the traditions of positivist medical geography with the cultural turn in geography in the 1990s and the incorporation of cultural and social theory into interpretations of health in place. Health geographers utilize a range of theoretical frameworks, methods, and concepts to probe the dynamic linkages among power, space, place, and time at different spatial scales. Using different examples to highlight the new approach to understanding health, this section will explain how health geographers have contributed to health discussions, often through policy, to alleviate health inequalities and improve health.

Introduction

Health geography emerged from the traditions of positivist medical geography with the cultural turn in geography in the 1990s and the incorporation of cultural and social theory into interpretations of health in place. Understanding health is complex. As set in its Constitution in 1948, the World Health Organization defines health as "the complete state of physical, emotional and social well-being and not merely the absence of disease or infirmity." This definition suggests that good health is utopian; under this understanding of health, an Olympic athlete who is physically fit and free from disease might technically be unhealthy if she is worried about, for example, her personal development or even a forthcoming bill. As health is complex, it has to be interpreted in a manner that endeavors to understand its nuances. Health geographers utilize a range of theoretical frameworks, methods, and concepts to probe the dynamic linkages among power, space, place, and time at different spatial scales of the globe, nation, region, home, and body (Atkinson et al., 2011).

Health geographers aim to understand questions of health, healing, and well-being through three key approaches. First, health geographers move beyond a spatial analysis of disease to consider the role that place plays in health. Second, the incorporation of cultural theory enables nuanced understandings of the way cultural beliefs and practices structure the place of health and healthcare provision. Third, health geographers borrowed from critical theory to provide insights into the way that people and places can be negatively affected by large-scale forces such as global firms or changing political frameworks (Cutchin, 2007), conjuring questions of responsibility at various scales. Moving beyond multilevel modeling or epidemiological mapping, health geographers utilize a range of methodologies including interviews, focus groups, and ethnographic engagement, often in combination. With new insights and approach, health geographers have retheorized previously marginalized health spaces, which has facilitated a reinterpretation of health in place in a manner that can contribute to health understanding, activism, and policy.

This article will first consider how health geographers used cultural theory to reconceptualize space and place, which provided new lines of critical enquiry and methodologies that enabled them to contribute to key debates and policies surrounding health and healthcare. These changes will be illustrated across varying spatial scales, beginning with the way that health geographers used social and cultural theory to reconsider the space of the human immunodeficiency virus (HIV) and its transmission. At the regional scale, the article will consider the debate surrounding the context and composition of place in health, highlighting key questions of structural power and responsibility. At the local scale, the place of home will illustrate health geographers' growing interest in care through the transformation of the home and the body as sites of caring.

Space and Place in Health

Geographers have always been interested in questions of space and place and the processes, interactions, and practices that occur within them. The 'cultural turn' of the mid-1990s shifted geographical focus away from utilitarian concepts of space as simple area descriptors, toward a more reflective understanding of the meaning, utility, and construction of space and place. Both medical and health geographers aim to alleviate health inequalities through an understanding of health and illness in place, but the two take different methodological approaches. Stemming from a culturally informed understanding of place, health geographers began to consider the roles that place, and the processes occurring within place, play in the making of and experiences of health (Gattrell, 2002; Williams, 1998). Unlike positivist medical geography, which conceived space as a blank canvas upon which medical subjects could be mapped, health geographers understand place as a complex of material, sociological, experimental, and philosophical phenomena that inform and affect health, healthcare, and health behaviors. There is still an appreciation of the physical attributes of places, as will be further discussed in the next section, but the experience of health in place is recognized through the social, cultural, economic, or political processes that simultaneously construct and affect the health space. Indeed, drawing upon the aforementioned World Health Organization's definition, far from being the mere absence of disease, health is an entirely personal, temporal, and fluid concept. As health knowledges are multiple and socially constructed in place, health geographers argue that such knowledges are not always best suited to an empiricist or positivist interpretation. This new socially constructed

understanding of health, and the role of place in health, enabled health geographers to rethink existing places of health.

Gesler's (1992) notion of therapeutic landscapes is perhaps the seminal example of this evolution in thinking. Used as a way to critically analyze the complex dynamics among place, well-being, and healthcare, therapeutic landscapes are places that are seen to be conducive to healing. Gesler's original thesis recognized that certain physical places, or geographical locations, have potential for physical, mental, and spiritual health promotion and for the process of healing such as Lourdes, France. With further development of the thesis, public health interest moved away from physical places of well-being (Lourdes, etc.) to considering the potential therapeutic or healing properties of other spaces such as gyms, prisons, parks, and wilderness (see Smyth, 2005). Within those spaces of healing, such as a park, the physical, social, and symbolic organization of the space is much more significant than its geographical location or physical constitution. The social impact of an individual appreciating the sense of peace she experiences through sunshine-strewn wilderness may have greater therapeutic benefit than the physical trees and fresh air; her temporal place-based experience constructs a place of healing. A health geographer's approach recognizes how the space promotes health, rather than just where it is or how it is physically constructed. Developing the thesis, such spaces of health dramatically vary in scale from a vast open wilderness to Grandfather's chair which, positioned by the window, perhaps enhances his health and well-being much more than a hospital could as a space of therapy (Gattrell, 2002). In health geography, therefore, place is more than a specific geographic location, empty environment, or a 'backdrop' for health interactions (Dyck, 1999: 247) but a place of process, practice, and meaning that is situated and socially produced in particular contexts; place thereby reflects and informs understandings of health, which, in turn, affects the interpretation of place. A good example is the aforementioned wilderness that brought such therapy to one individual, but could easily be a space of fear for another.

A constructivist understanding of place and health suggests that neither can exist independent of the actions or factors that constitute and are contained within it. As Gesler (2003: 1) put it, "healing and place are inseparable." Health actions are embedded in broader spatiotemporal social, historical, cultural, economic, political, and often power-bound contexts (Smyth, 2005) which are informed by, and constitute, place. Power impacts place and the health actions within them at various scales through broader structural processes in play such as governance by large corporations or legislation and also through, for example, individual power to assert health changes over the body. The following sections will apply the new theoretical approach to understanding health in place and highlight how health geographers have contributed to the discussion.

Inequalities and HIV

Since the World Health Organization issued its Commission on the Social Determinants of Health, 'Closing the gap' in 2008, questions of global health inequalities have risen significantly in importance as both a subject for academic research and a focus of international policy development. While global levels of poverty are decreasing, inequalities are increasing with significant implications for health. Curtis (2004), among many others, argues that the geographies of health inequalities are a long-established and central tenet of research in medical geography but one that has significantly grown in opportunity through the new health geography. A health geographer's understanding of HIV provides a good global example.

HIV is transmitted through the exchange of bodily fluids, blood, semen, vaginal secretions, and breast milk. The virus attacks the immune system of infected individuals which impairs their capacity to resist infection. When the infected individual's immune system has a CD4 cell count of below 200 cells mm^{-1}, the person is clinically diagnosed as having the acquired immune deficiency syndrome. According to the World Health Organization, since the beginning of the epidemic almost 75 million people have been infected with the HIV virus and about 36 million people have died of HIV. HIV is largely associated with areas of the developing world, such as sub-Saharan Africa where inequalities in healthcare access exacerbate the rate of HIV-related death. With the first outbreak of the epidemic, epidemiologists and medical geographers mapped the incidence of disease transmission which showed the spatial distribution but did little to explain transmission.

In many societies, particularly during the 1990s and early twenty-first century, HIV was a disease of stigma and shame due to its association with drug use and unprotected sexual intercourse. Fear of ostracism or discrimination prevented many people from being treated for the virus. The stigma then became a barrier to knowledge to prevent HIV transmission and could prevent access to appropriate treatment. Despite the expected low recording of transmission rates, the number of people living with, or dying from HIV was growing rapidly and exacerbating socioeconomic inequalities. Among others, Craddock (2000) stressed the need to move beyond a structural analysis of HIV in geographical location to incorporate social theory to examine the power-bound social health *place* of HIV and why it was that, for example, some groups were more vulnerable to HIV transmission, or might be less likely to access treatment or prevention knowledge. Highlighting a health geographer's use of theory, a feminist analysis enabled contemplation of the female body that in rural Uganda had few sexual rights and thus became a vulnerable place of disease transmission. As a good example, developing the health geographer's approach, Kuhanan (2010) considered the place of high HIV incidence in Rakai, Uganda. Rather than just mapping disease incidence, Kuhanen recognized that the long history of the epidemic needed to be understood as a social and economic problem, as well as an epidemiological one and considered sexualized public spaces as key places of HIV transmission. Kuhanen reflected upon the dramatic move away from the traditional colonial control over female movement and space and the growth of rural-to-urban migration, which instigated informal sex economies as women struggled to earn a living. While reconstructing the power-bound identity of 'women' in place, Kuhanan (2010) identified that the shift in roles of women and the growth of the informal sector

constructed places of HIV transmission and in turn created places of transmission which informed behavior. This analysis also highlights the key role that geographic scale plays in health geography. Global distributions of HIV might be decreasing in figures but do not reveal the growing rates of inequality in standards of living, or explain rates of transmission.

Seeing the site of HIV transmission as more than simply a geographical location but also as a power-bound space that is constructed by both health behavior and constructs, it reveals a very different landscape of transmission than does a purely epidemiological approach. Health geographers have thus been able to contribute to HIV discussions to aid policy: Craddock (2007), for example, considered the role of pharmaceutical companies in the geographies of HIV in Africa; Ingram (2008) considered the political construct of HIV as it was framed as a biosecurity emergency in global governance strategies that was key in the intersection of HIV, immigration, national security, and notions of refugee and asylum; and Gwanzura-Ottemoller and Kesby (2005) considered the place of HIV from the perspective of young people and their negotiation of safe sexual practices.

The Regional: Context, Composition, and Air Quality

While understanding that place and healing are inseparable, a regional example demonstrates that place itself matters in a true understanding of health. Macintyre et al. (2002) discuss the debate that arose in the early 1990s among health geographers over the relative importance of people or place characteristics in shaping people's health experiences. Although health spaces are constructed through behavior and certainly are not mere physical containers of healthcare interaction, places do affect health. That impact can be through the physical attributes of place, known as contextual effects, which are the direct effects of air quality and landscape but also indirect impacts through, for example, the availability of healthy food stuffs or recreational facilities. Compositional factors of a place can also shape health; these factors include the people themselves and key attributes such as gender, ethnicity, socioeconomic, and employment status. This long-standing and, as Smyth (2008) would argue, uneasy, debate questions how geographical inequalities in health can be explained by the composition of a population and the context of the place. The varying impact of context and composition of place to explain spatial variations in health has implications for who has the responsibility to change variables that are impacting health.

More recently, the context versus compositional debate has become less polarized as the nuanced approach of health geographers considers health in place and utilizes a variety of methodologies to understand questions of health inequality such as access to health services, obesity, and pollution levels (Macintyre et al., 2002). Day (2007), for example, considered how place is significant in the experience of environmental hazards but particularly considered the ways in which inequalities are exacerbated through exposure or risk. Applying the mixed methodology of a health geographer to consider place in health, Day studied four different neighborhood areas in the London Borough of Barnet which had a wide variation in air pollution levels and indeed privilege. The contextual understanding of health in place highlighted the high levels of air pollution in the boroughs but, conducting the study over 2 years and using semistructured interviews, Day identified a disjuncture between peoples' judgments of air quality (as gleaned from the interviews) and meteorological measures of air quality. The study showed that air pollution was understood and experienced both through, and as part of, multidimensional place and provided crucial insights into the production of some inequality of experience. Day's approach recognized the need to pay more attention to the broader understanding of place and consider both the contextual and compositional factors in trying to improve living environments and alleviate inequality. Furthermore, Cairns (2012) utilized data that challenged the context versus compositional debate by suggesting that some economically deprived areas in England defied the trend of a positive and graded association between area deprivation and health outcomes in Britain. Their study revealed that certain areas with a high ethnic density had lower than expected mortality rates due to positive social support networks or 'health resilience' which they found to have a positive impact on health.

Cutchin (2007) furthered this argument by highlighting the need to bridge the epidemiological understanding of health in place with a more social understanding but added the necessity to consider how a health geographer's utilization of critical theory provides insights into the way that people and places can be negatively affected by larger scale forces, such as the state or international organizations. Cutchin moved beyond the classic therapeutic landscape literature and applied a number of health geography approaches including cultural ecology (which considers the notions of culture and environment interaction) to the situation of Texas City where he was considering how the health of local residents was affected by the stress response created by the petrochemical industry and other stressors. The study drew on context and composition by contemplating the physical environment, particularly petrochemical production, as well as the status, social ecology, and social relationships of the population. Developing the therapeutic landscape concept, Cutchin (2007) discussed how culture can become material through the landscape, which in turn can be read as an often power-bound materialization of that culture. The example here was how the memory of a terrible, large-scale disaster where a ship caught fire and exploded was physically inscribed on the landscape through memorials and parks; in turn the landscape could be read as a space of disaster with resultant impacts on residents. Cutchin also highlighted the insight of a political ecology approach where traditional ecological views are expanded within a political economy perspective to consider the structures or agencies that shape environments and health risk for populations, for example, the availability of green spaces within a council borough. Applied to the Texas City situation, this approach returned to the power-bound question of responsibility for health and how, in this case, the petrochemical industry had a responsibility for the impact that it was having on the health of the population both directly and indirectly. Cutchin's study highlights how different approaches within health geography enable a more holistic perspective of place and process on the question of health and provide evidence of the interplay of values and power from various geographic scales.

Caring, Home, and Self

Since early in 2000, health geographers have begun to consider the intricacies of the interrelationships between people, places, and materialities in different spaces of care in an effort to critique the unproblematic conceptualization of care as it is understood within a medical model (see Atkinson et al., 2011). Lawson (2007) explains how we live in times defined by relentless right-wing extension of market relations into all spheres of our existence. A consumer- or client-related view of healthcare, university education, care for the elderly, support for the working poor, or environmental protection – generated by the market-orientated approach – challenges not only how such services are perceived and delivered, but where they are delivered. The reduction in public provision of care and social support, for example, coupled with a neoliberal ideology based on individual over collective responsibility, has challenged more traditional understandings of care delivery, particularly in care of the elderly (Cutchin, 2003). By considering the role that place plays in the health and healthcare delivery, health geographers have questioned notions of responsibility in caring for the elderly, where care should be delivered, and the impact that those changes have had. Addressing these questions of caring in place illustrates how health geographers have been able to traverse the theoretical, empirical, and policy gulf and use their nuanced understanding to actively influence policy, engage with the public, and make an impact.

In many developed countries, from the latter half of the twentieth century, the implementation of policy focused on aging and community care in place, re-centered the main space of care for vulnerable people from institutional place (hospitals or residential homes) into domestic space, and by default into the realm of women (Milligan et al., 2007). With the relocation of care the boundaries between a place of healthcare delivery and a domestic space of home blur, which in turn challenges existing knowledge systems and (re)constructs the identity of the carers in relation to the care recipient. Such challenges can alter relationships and perceptions of the meanings of home. For example, if an infirm grandmother moves into her daughter's family home, the relationship between mother and daughter can change into one of dependent but informal care delivery; in turn the family home could be transformed into a place of informal care delivery through medical or caring paraphernalia and renegotiated relational identities (Dyck et al., 2005). The home can potentially become a place of marginalization and oppression in which carers, particularly women caring for long-term health needs, can feel isolated and disconnected from the outside world. McDowell (2004) discusses how that caring can be quantified; for example, care homes make substantial profits by creating spaces which simulate home caring for the growing elderly population; the conversion into a commodity of the day-to-day care that is so taken for granted or is often poorly paid work. Health geographers' interpretations of care delivery for the elderly and how that is impacted by place, and in turn affects place, have contributed to healthcare delivery in a variety of outputs. Wiles and Wild (2011), for example, have made policy recommendations about the ideal place(s) to grow older based on research conducted on two very different communities in Auckland and South Waikato. Dyck's 2014 research on migration, health, and well-being was used to produce a DVD that is being used by two mental health counseling groups in the Borough of Greenwich, London, and by community organizations. Moreover within the discipline, the necessity or moral obligation to care through ethical and impactful research has become both a driving force and a measure of success (see Lawson, 2007).

Health geographers' understanding of care has cast considerable critical insight into retheorizing the space of the body as a place of health and healthcare. The body itself is far from a new focus of analysis; literature is abundant across a host of disciplines from sociology to sports science addressing questions such as diet and fitness, cosmetic modification, sexual health and its expression, drug use in sport, and an increasing awareness of risk discourses surrounding the body (see Lupton, 2003), much of it stemming from feminist literature of the 1980s (see Haraway, 1987). The body is a space of health interaction, experience, and expression, which, beyond blood and bone, is constructed by cultural, political, historical, and indeed personal process and discourse. Bodies are intrinsically bound up with our sense of identity; they are cognitive, subconscious, and emotional as well as being experienced through physical flesh. A poststructural analysis of a body considers it as a metaphor for social organization and social anxieties which generate questions of responsibility. Bodies get sick, they can get strong, they are potentially dirty or leaky, they are gendered, sexualized, a space of production and reproduction, ultimately a site for death. Bodies thus are conceptualized as spaces in need of regulation and control, whether by an individual or a third party such as the state, hospitals, beauticians, or schools, and can be read as personal spaces that represent global processes (Atkinson, 2011). As reflective of those processes, the body is always an ongoing malleable project that is never finished.

Health geographers recognized that, with constructionist understandings of place and health and multiple power-bound knowledges, the body could no longer be considered a given – and often taken for granted – reality, but a product of certain kinds of knowledge and discourses that are subject to change. Bodies are shaped by social relations but also play a role in the construction of those politically, historically, and culturally bound relationships and can thus be read as a landscape of those power-bound forces. Health geographers have contributed to the broader body discussion focusing on the gendered (e.g., Binnie, 2011) or disabled body (see Gleeson, 1999), which has developed with understandings of the commodification of care (Green and Lawson, 2011) to consider caring for the body, care through the internet (Atkinson and Ayers, 2010), or aesthetic surgery (Atkinson, 2011).

Conclusion

Prompted by the cultural turn in geography, health geographers moved beyond the epidemiological understandings of the spatial analysis of disease to recognize the role that place plays in health and its understandings. While the physical attributes (the context and composition) of place were still recognized, the new health geography retheorized place as a complex material, sociological, experimental, and

philosophical phenomenon that both constructs and is constructed by health. By incorporating more cultural theory into the place-based analysis, health geographers were better positioned to understand the nuanced processes and practices that were shaping health behavior and inequalities – as illustrated here by the feminist landscape of HIV transmission. Further engagement with critical literature enabled health geographers to expand the analysis of health from the individual scale and consider the broader structural processes and powers that construct a potentially negative landscape of health, such as the petrochemical plant in Texas, which raises key questions of roles and responsibility in maintaining health. The new approach enabled health geographers to retheorize previously neglected or sensitive spaces of health, such as the home, and unveil complex questions of power and identity in place. Kearns and Moon (2002) argue that health geographers still have some way to go to be recognized as real contributors to health policy compared to their medical counterparts. Yet, the broader theoretical shift not only has witnessed the marked separation of health geographers from medical geographers, but also has opened up new lines of critical enquiry that, as illustrated earlier, have enabled health geographers to make some significant contributions to the policy agenda from global spaces to the personal health place of the body.

Abstract

In the 12 years since publication of the previous issue of this volume, the world has changed significantly. In addition to further widening of many of the disparities in health previously described, the impact and implications of the still evolving global economic crisis and of climate change have led to increasing recognition of how the 'development' agenda has failed, and that global health is one of the major challenges for the twenty-first century (Benatar and Brock, 2011). World population has increased to 7 billion people, half of whom continue to live in severe poverty (on less than US$2–3 a day), most in constant hunger and under squalid conditions, with little prospect of significant improvement unless new solutions are envisaged. This article discusses the health of citizens of very poor countries and the global interdependence of the health of all peoples, including the privileged.

Global Health Trends since the 1940s

Human health and well-being worldwide are profoundly affected by complex interactions between economic, social, and political forces. Some historical facts about tuberculosis in rapidly industrializing countries provide an illuminating example. With better nutrition and living conditions, the annual mortality rate from tuberculosis in the United Kingdom fell from 500 per 100 000 people in the early 1700s to 50 per 100 000 in the early 1940s before antituberculosis medications were discovered. Health in general also improved significantly during this time and life expectancy at birth increased from 37 years in 1750 to 48 years in 1940 (McKeown and Record, 1962; McKeown, 1976).

Between 1945 and 1970, another consolidating wave of advances in health status was associated with reconstruction of a global economy that had been severely compromised by the Great Depression and two devastating World Wars. Growth of the middle class was promoted by a spirit of solidarity forged through access to jobs, universal access to education, and health care and the provision of other social services funded by progressive taxation within well-regulated economies. This is the context within which modern medical advances could be effectively applied to improve health and facilitate the eradication of many epidemic infectious diseases, as exemplified by further reduction in the annual death rate from tuberculosis to about two per 100 000 in the UK, and increase in life expectancy to about 75 years. During this time, health and life expectancy also increased in many poor and colonized countries (World Bank, 1993).

With the introduction of financial deregulation, privatization, and liberalization of global trade in the late 1970s, the general trend in health globally followed two diverging pathways. One was associated with boosted economic growth and the application of ongoing advances in medicine for the benefit of the top 20% of the global population (about 1 billion people) living predominantly, but not exclusively, in wealthy countries. The other was characterized by impediments to economic growth for a poor majority, deterioration in their living conditions, and curtailment of public health services (Birn, 2011; Labonte and Schrecker, 2011)

Relationship between Health and Wealth

The Global Political Economy and Health

While the twentieth century was considered by many to be the most successful in world history, with spectacular achievements in science, technology, and health care it is necessary to focus on the dark side of progress – as reflected in ever-widening disparities in economic and health status (Labonte and Schrecker, 2011), the extent of expenditure on weapons of war (Strategy Page, 2009), and the social construction of systems that abuse human rights (Farmer, 2003; Benatar and Doyal, 2009; Benatar, 2011). In the past 150 years, world population has grown more than sevenfold and human consumption has increased more than 50-fold. The USA, with 5% of the world's population, accounts for about 24% of annual global energy consumption compared to China with 20% of the world's population using 10% of global energy in the early 2000s, rising to 20% by 2012 and predicted to approach 30% by 2020 if China's growth continues at the same pace (Sharma, 2012 cited by Zakaria, 2012). Similarly, within health care, even a nation that spends over $7000 per person per year on health care is unable to provide access for all citizens to modern medical care (Iglehart, 1999).

The world at the beginning of the twenty-first century is thus characterized by widening disparities in economic and health status (within and between countries), and by suffering, conflict, and alienation associated with pervasive social forces (Birn, 2011; Labonte and Schrecker, 2011; Benatar et al., 2011). Erosion of the economy of many poor countries, under the impact of globalization and the 'debt trade', underpinned by neoliberal economic policies, has obstructed the introduction of effective forms of modern medicine into many poor countries and thus prevented achievement of widespread access to even basic health care for billions of people (Rowden, 2009). Third world debt requires special mention. Insistence on repayment is unconscionable when one considers the ways in which such debt has been created, that third world debt is a small component of total world debt and can never be repaid, and that in sub-Saharan Africa four times as much is spent on debt repayment each year than on health and education combined, (Pettifor, 1996; Rudin and Sanders, 2011). The term structural violence is used to

describe how the ideology lying behind such social changes pervasively affects life and health adversely (Farmer, 2003).

Globally, privileged people (20% of the world who have benefitted most from progress since the early 1900s) have become less aware of the social determinants of health, and their focus has shifted to a biomedical and increasingly (expensive) technological approach to health (Daar and Singer, 2011). Health care has become a marketable commodity within a so-called free market system, where everything is calculated, planned, and delivered within an economic and regimented managerial mindset (Callahan and Wassuna, 2006; Relman, 2007). Over time, western biomedicine has in many ways shifted from being a caring, social function, provided through universal access as a social duty to all citizens of equal moral worth, to a profit-driven commercial enterprise run by businesses in the private sector, and poorly managed, cost-containment exercises in overwhelmed public sectors.

The emergence of new diseases, most prominently HIV infection in 1981 and the Ebola virus in 1976 with its recent major epidemic that afflict predominantly those marginalized by poverty (almost 80% of HIV positive persons and almost all infected and dying from Ebola live in some of the poorest countries in the world (Fauci, 2014)), has been attributed to the social and environmental niches created by the nature of the global political economy and its ideology (Lee and Zwi, 1996; Quammen, 2012).

The changing spatial dimensions of human relations resulting from urbanization, migration, travel, ethnic conflict, and displacement of people and refugees, facilitates the spread of such diseases from which no one should feel immune. Failure to appreciate such associations will result not only in failure to control such diseases as HIV/AIDS (and tuberculosis), but more importantly will probably favor the emergence of new infectious diseases in the future (Benatar, 2001).

Modern consumption patterns and health care practices are thus neither universalizable nor sustainable. Their effects on the environment and climate are adverse for both high- and low-income countries and can no longer be ignored. The World Health Organization (WHO) estimates that globally, for the year 2000, there were 150 000 deaths and 5.5 million disability-adjusted life years (DALYs) lost due to climate change (WHO, 2013). Global environmental change is predicted to cause 500 times more loss of healthy life years in low-income African countries than in Europe (McMichael, 2012).

Increasing Inequalities in Wealth and Health

While it is now well established that there is a definite relationship between wealth/poverty and health/disease, these relationships are complex and not linear. For example, one of the wealthiest nations in the world (the USA) has worse health statistics (infant mortality and longevity) than some other highly industrialized countries, and Kerala, a particularly poor state in India, has achieved lower infant mortality rates and greater longevity than many wealthier countries (Labonte and Schrecker, 2011; Birn, 2011). Both absolute and relative wealth affect health. Among the developed countries it is not necessarily the richest societies that have the best health, but rather those with the smallest income differentials between rich and poor (Wilkinson and Pickett, 2009).

The social circumstances influencing women's and children's health begin with the physical, mental, and nutritional states of women during pregnancy and childbirth and continue throughout life (Bhutta and Black, 2013). Care of infants, education and nurturing of children, opportunities for further study during adolescence, and access to rewarding work are all enhanced by maternal literacy, as demonstrated in some relatively poor countries with high levels of female literacy. Access to adequate nutrition, clean water, sanitation, housing, and basic health care is essential.

Poverty (defined as lack of economic resources, lack of education, lack of access to basic life resources such as food water and sanitation, and lack of control over the reproductive process) directly accounts for about 18 million, or one-third of all human deaths each year (Pogge, 2005). Poverty leads to poor health, which in turn aggravates poverty – through the following:

- A bad start in life, for example, undergoing brain or other damage *in utero* through maternal deprivation or abuse, poor antenatal care or inadequate access to safe delivery
- Physical and emotional deprivation during childhood and adolescence
- Inadequate education and lack of exposure to the positive social and environmental forces required to promote effective adolescent maturation
- Inadequate access to the basic living conditions required throughout life for good health (clean water, safe sanitation, adequate nutrition, housing, and clothing)
- Lack of training for work that will allow development of the capacity to become an independent adult
- Lack of a sense of belonging as a valued citizen

All of the above, in different combinations, adversely affect the lives of almost 4 billion people who live below what has been defined as the 'ethical poverty line' of $2.80–3.00 per person per day. These vulnerability-promoting features, while long-understood, have only recently been formally acknowledged by the World Health Organization in its report on the Social Determinants of Health (WHO, 2009). They are largely determined by socioeconomic, politicocultural, and organizational influences sustained by legally enforceable processes that have been locked into place through international legal mechanisms, such as trade laws and tax regulations, since the second half of the twentieth century under the influence of neoliberal economic policies (Rowden, 2009; Gill and Bakker, 2011; Birn, 2011).

Continued use of the terms 'developed' and 'developing' countries, implies a linearity of progress toward a condition that has been achieved by some countries but not others. It is an increasingly inappropriate term, as it misguidedly equates development with economic status in terms of average per capita gross national product (GNP) or the level of industrialization. The more sophisticated model of development (e.g., that used in the United Nations Human Development Report, 1991) emphasizing achievements in health, education, female literacy, gender equality and political liberty, more accurately reflects the real human development required. However, it should be acknowledged that even such development indices are incomplete, as they leave out other important aspects of human flourishing.

On the one hand, high-income, or so-called developed, countries may not have what many would consider very

important aspects of development. For example, they may lack a commitment to reducing the impact of consumption on ecology, concern for the adverse effects of opulent and aggressive lifestyles on billions of people in other countries, and fail to provide universal access to health care.

On the other hand, the achievements made by some so-called developing countries despite their low-economic status is impressive. For example, in Kerala, India the levels of health achieved beyond that expected from economic status alone illustrates the striking impact of improving human capital resources such as female literacy and female empowerment in tandem with a focus on primary health care (Government of Kerala, 2005; Birn et al., 2009).

Sustaining and amplifying such examples is a major challenge, but unlikely to be met without new ways of thinking about health and the global political economy. Such considerations reveal the inadequacy of the terms 'developed' and 'developing' countries, and beg the question of how the idea of sustainable development could be changed toward the more reasonable idea of developing sustainability (Bensimon and Benatar, 2006).

Economic Inequalities

At the beginning of the twentieth century, the wealthiest 20% of the world's population were nine times richer than the poorest 20% of people (BMJ, 1999). This ratio increased progressively – to 30 times by 1960, 60 times in 1990 and to well over 100 times by the early 2000s. The Gini coefficient (a measure of economic inequality) increased from 0.25 to 0.4 in the UK in the past three decades, from 0.38 in 1968 to 0.47 in 2010 in the USA and from 0.6 in 1995 to almost 0.7 in 2009 in South Africa. As of 2011, almost half the world's population lives on less that $1000 per year, and more than a quarter of the world's population lives (on less than $1.5 per day) under conditions of absolute poverty (Bhatt, 2011). In the middle 2000s, approximately 1.75 billion people in the 104 countries covered by the Multidimensional Poverty Index lived in multidimensional poverty that is characterized by at least 30% of the indicators reflecting acute deprivation in health, education, and standard of living (Human Development Report, 2012).

Widening disparities within and between countries in wealth and health during the twentieth century and into the twenty-first century were aggravated by the implementation of neoliberal economic policies in the late 1970s that led into the most severe economic crisis since 1929. As a result, the price of food increased, and an additional 100 million people were thrust into extreme poverty since 2008. As of 2009 data, a billion people live under such conditions (Benatar et al., 2011; Blas, 2009). While tens of millions of people, including many children, die every year of starvation – in a world with enough food to feed all – greater attention is being directed toward providing antiretroviral drugs to all who need these than to saving the lives of those who are starving. The very positive impact of widespread availability of antiretroviral drugs starting in the late 1980s is a testament to the success of the biomedical approach to health that dominates in wealthy countries where the social determinants of health are largely taken for granted. Yet this successful use of antiretroviral treatment eclipses the fact that in low-income countries improved health is generally more dependent on social forces than on the application of modern health care methods.

Health Inequalities

In the early twenty-first century, patterns of disease and longevity vary markedly across the world (Labonte and Schrecker, 2011, **Figure 1**, **Figure 2**). Low-income countries bear over 80% of the global burden of disease in DALYs. This burden is likely to increase as the epidemiological transition progresses, with added disability and suffering from non-communicable diseases such as vascular disease, malignant neoplasms (especially of the lung associated with smoking), neuropsychiatric disease, accidents, and trauma (Lancet, 2012). The lifetime risk of dying from complications of pregnancy and childbirth ranges from 1: 11 000 in Canada to 1: 7 in Niger, and to 1: 76 in the developing world as a whole. Under 5-year-old child, mortality rates range from less than two per 1000 live births in high-income countries to over 170: 1000 in Africa. Life expectancy at birth (LEB) in countries ravaged by HIV/AIDS has fallen to 45 years (and continues to fall) while in high-income countries LEB is over 80 years and rising. It is estimated that in 2010 about 34 million people were living with HIV/AIDS (about 3.5 million of these children), that 1.7 million died of HIV/AIDS that year and about 2.5 million became newly infected each year (Avert, 2012).

Changes in patterns of disease with widening disparities in health and life expectancy are also taking place within high-income countries. Reduction in the frequency of infectious diseases combined with excessive consumption of salty and high-calorie food and less exercise is leading to growing rates of morbidity (sickness/illness) and early deaths from diabetes, stroke and cardiovascular diseases. These features illustrate the degree to which many of the contradictory aspects of global health are part of a wider pattern connected to the inequality arising from the structures and values of modern Western societies (Wilkinson and Pickett, 2009). Changing ratios of young-to-aged people and the health care implications of care for large numbers of old and frail persons, add yet another demographic health challenge for high-income countries in need of more carers, and for low-income countries from which health care workers are actively recruited (Eckenwiler, 2012). In addition, climate change will disproportionately affect the health of the poor (Friel et al., 2011).

Even in high-income countries, improvements in physical health since the mid-twentieth century have not been matched by improvements in mental health. In the late twentieth century, mental illness accounted for 8% of the global burden of disease measured in disability life years (Desjarlais et al., 1995). An updated assessment suggests that mental, neurological and substance abuse disorders account for 17% of the global burden of disease (Collins et al., 2011, *Nature*). The inadequacy of the knowledge base about mental disease (compiled almost exclusively in North America and Europe) to adequately explain and effectively treat psychiatric diseases in other parts of the world poses formidable challenges for progress (Summerfield, 2008)

Policy Issues

Militarization and the Social Construction of Human Rights Abuses

Annual global defense spending fell to less than $1 trillion after the Cold War ended in 1991, but has grown by almost 50% (to over $1.3 trillion) in the past decade (about 2.5% of global Gross domestic product), with the greatest increase in expenditures (up 62% in the last decade) in the Middle East (Strategy Page, 2009). Industrialized countries spend on average 5.3% of their GNP on the military but only 0.3% on economic aid to developing countries (Sivard, 1996), well below the target of 0.7% of Gross National Income (GNI) of the Development Assistance Committee countries (Zwi, 2011). The arms trade, with its link to economic aid, has contributed significantly to the escalating number of wars, conflict, and

widespread torture since the Second World War, and it has displaced over 25 million people. The war in the Democratic Republic of Congo that started in 1993 resulted in 3.3 million deaths of which about 200 000 were directly through violence, and the remainder from the indirect effects of war on the country (Mahmudi-Azer, 2011). Some years ago, it was estimated that the annual budget of the WHO was equivalent to 2.5 h of global military expenditure.

Health Care Expenditure and Health Outcomes

Since the 1960s, major advances in medicine and technology have been associated with escalating expenditure on their application in health care – most of this in highly industrialized countries. In recent decades about 90% of annual world expenditure on health care was spent on about 16% of the world's population who bear approximately 7% of the global burden of disease (in DALYs) and less than 10% of medical research expenditure was on health problems of the developing world (Iglehart, 1999). In the first decade of the twenty-first century, annual per capita expenditure on health care ranged from more than $8000 in the US to less than $15 in the poorest countries. The poorer WHO regions like the Africa Region and the South-East Asian Region comprising 38% of the world's population, account for the largest share of the global burden of disease (over 50% of global DALYs lost), and spend only 2.5% of global health resources (WHO, 2011).

These are examples of global injustice that we should surely find intolerable if we have a real commitment to universal human rights and human dignity. Vaccine development programs and drug donation programs for poor countries, admirably promoted and supported by pharmaceutical companies, are necessary but insufficient responses to such injustices. However, modest increments in economic status, combined with provision of a basic health care package, have the potential to improve health in poor countries significantly. Economist Jeffrey Sachs has estimated that a tax of one cent on every $10 earned applied to the wealthiest 1% of the world's population would generate the $35 billion required to increase annual per capita expenditure on health from $15 to $50 per year for the poorest billion people in the world (Sachs, 2009).

Even though some parasitic diseases (for example, onchocerciasis, schistosomasis, and lymphatic filariasis) could be controlled by mass vertical treatment campaigns using inexpensive drugs, the infrastructure required to provide such coverage is inadequate. Moreover, effective vertically organized services for these specific diseases and others like HIV/AIDS can pose the danger of impairing the development of sustainable, horizontally organized and well integrated health delivery systems. Effective treatment of diseases such as tuberculosis, leprosy, and HIV/AIDS requires more complex infrastructures than can be afforded on current health care budgets in poor countries. However, the achievement of improved health is not merely a resource issue even in rich countries – as exemplified by comparative health statistics around the world (Wilkinson and Pickett, 2009; Labonte and Schrecker, 2011; Simpson, 2012), and by formal acknowledgment of the greater impact of well organized health services (McKee, 2011) and other social and societal forces on health (Birn, 2011).

Access to Health Care, and the Nature of Health Care Systems

Many countries consider access to at least a minimum package of health care as a basic human right that nation-states should be committed to providing for their citizens. Some form of equitable access to health care is provided in all Western European nations and in Canada. Medical care, delivered as a marketable commodity, albeit with considerable state assistance for the poor and the aged, is the example that has been set by some of the wealthiest nations in the world. However, many citizens have inadequate access to health care. While recognizing that private/public alliances cannot be avoided and indeed may be beneficial, Buchanan has provided cogent arguments for the nine elements he considers essential for a just health care system. He argues further that achieving a just health care system as a cooperative between the public and private sectors requires an organization, such as the state, to act as a coordinator and guarantor of equitable access to care and fair distribution of costs. A balance between private and public medicine with appropriate coordination could overcome the deficiencies of both systems (Buchanan, 1995).

The effects of intensive privatization, aided and abetted by the structural adjustment programs promoted by the International Monetary Fund and the World Bank, have been much more marked in low-income countries and have had severe adverse effects on health and access to health care. Acknowledging the need for, and the right to, universal access to a basic health care package and achieving this goal pose challenges for the future. The WHO's renewal strategy for health-for-all places emphasis on equity, solidarity, and appropriate technical, political, and economic strategies that could promote health and sustainable health care systems as central to development. Here too an appropriate balance needs to be struck between public and privately funded medicine. How this balance can be struck and how health can be coordinated within an effective strategic alliance between many parties remain hotly debated subjects. The example of making antiretroviral drugs available to millions of people in poorer countries is encouraging (UNAIDS, 2011).

Traditional Healers

Despite the pervasiveness of Western influences, traditional healers have survived and play an increasing role in some countries. For example, while there are about 25 000 Western trained medical practitioners in South Africa, and Western medicine has a powerful foothold in this middle-income country, over 200 000 traditional healers carry out a thriving trade. In part, this may be attributed to the emphasis in traditional medicine on the disruptive societal behavior of individuals as an explanatory causal factor in disease. Increasing contact and collaboration between Western medicine and traditional healers as well as other complementary and alternative healers is to some extent being encouraged. It has been recommended that the potential impact of their contributions to health in the broadest sense (Pretorius, 2012), especially in association with a primary health care approach should be brought into an ongoing pluralistic health care system rather than being ignored (Engelbrecht and Van Rensbug, 2012).

Prospects for the Future

The still unfolding global economic crisis (Benatar et al., 2011) together with the very ominous implications of climate change (Oreskes and Conway, 2013) are stark reminders of the unpredictability of progress and the threats to much that is valued in Western civilization. Many hope that exponential increments in genetic information and other new biotechnological advances could be applied to medical practice and improve health. However, we need to seriously contemplate whether faith in such new power is exaggerated and, even if realized whether it will be used for the benefit of all humankind or whether it will be reserved for a privileged minority.

Advances in human health globally in the twenty-first century and achieving real improvement in the lives of all people throughout the world will be dependent on acknowledging many adverse features of modern life. Acquiring a deeper understanding of the forces promoting health and diseases in developing countries needs to be coupled to a commitment to address these forces and how they could be reshaped to achieve health and human flourishing on a wider scale (Gill and Bakker, 2011; Gill, 2012; Schweickart, 2012).

New paradigms of thinking and consequent innovative policies and action are also required to promote widespread human flourishing. This will entail development of new social structures and using available resources more effectively. Within health care reducing some of the massive wastage associated with delivery of health care has been shown to be very effective (Drumm, 2012). New approaches will also need to be applied to many other activities in modern life. In brief, there is a need to find ways of doing better with less! (Benatar, 2013)

Abstract

Insurance can be defined as a contract where the subscriber makes regular payments to the insurer in exchange of the promise of indemnity against specified risks. In health insurance, the specific risks covered are the financial costs of the treatments needed after an illness or an accident. The economics of health insurance is well developed and identifies a series of challenges, which can seriously jeopardize the proper functioning of health insurance markets based on private contracts. It is indeed rare to observe health systems that do not rely on some degree of government involvement. In this article, the theoretical and empirical challenges to health insurance markets will be described and discussed. Subsequently, we will provide a short description of the characteristics of the most significant health systems around the world, linking these with the issues emerging from the economic analysis.

Introduction

Insurance can be defined as a contract where the subscriber makes regular payments to the insurer in exchange of the promise of indemnity against specified risks. In health insurance, the specific risks covered are the financial costs of the treatments needed after an illness or an accident. The health insurance contract can be signed by either the individual subscriber or a sponsor, for example, the employer or a community organization. The insurer can be a private for-profit organization, a private not-for-profit organization, or the government (Claxton, 2002).

A health insurance agreement usually specifies the value and the form of the following:

- Premium: the monthly or annual regular payment to be made by the subscriber;
- Coverage: the type and the limits of the medical expenses that can be reimbursed;
- Deductibles: the limit below which medical expenses are not reimbursed. The insurance pays the difference between the medical bill and the deductible;
- Copayment or Coinsurance: the out-of-pocket payment to access an insured medical service. In copayments, this amount is fixed; in coinsurance, it is a percentage of the medical bill; and
- Network providers: the list of accredited providers (for example, hospitals, clinics, or general practitioners) selected by the insurer. In order to get coverage, medical services must be provided by the institutions included in the network.

The economics of health insurance is well developed and identifies a series of challenges, which can seriously jeopardize the proper functioning of health insurance markets based on private contracts. It is indeed rare to observe health systems that do not rely on some degree of government involvement. In the following, the theoretical and empirical challenges to health insurance markets will be described and discussed. Subsequently, we will provide a short description of the characteristics of the most significant health systems around the world, linking these with the issues emerging from the economic analysis.

The Market for Health Insurance: The Basic Framework

Why do people buy health insurance? When it comes to important issues like health and health-related expenditure, people are mainly risk averse (Arrow, 1970). Formally, a rational individual is risk averse if she prefers to gain X for sure rather than participating in a lottery whose expected value is X. In other words, people tend not to like risks and are willing to give up part of a certain income in order to avoid it.

The definition of risk aversion applies directly to the demand for health insurance. Imagining the future health situation of a subject as a lottery, health insurance requires that a person should be willing to give up part of her own income (insurance premium) in the present in exchange of a (partial) insulation from the risk of getting ill and incur monetary, physical, and psychological losses in the future. This can be a chosen option only if the person is risk averse.

In the baseline economic model of health insurance markets, risk averse individuals are assumed to be perfectly informed about the parameters driving their own choice. They know about their probability of getting sick and they know what losses they will incur in that case. Indeed, the assumption of perfect information of the insurance subscriber is common in many studies (Phelps, 2010). Similarly, the baseline model implicitly assumes that risks are correctly perceived. Not only do people have information about the risks, but they also interpret it correctly. In other words, in the baseline framework, problems of too much or too little confidence or any other source of misperception are ruled out a priori.

Although rational individuals choose to insure against health risks, market outcomes and equilibria depend also on the supply side. Economic theory has clarified that three main assumptions are needed for the provision of insurance through private markets to be efficient. First, administrative costs or any other cost outside the agreed reimbursements (these costs are also known as *loading factors*) should be small. Second, firms should be risk neutral. Last but not least, firms should compete on premiums (Einav and Finkelstein, 2011). This in turn assures that premiums are *actuarially fair*, i.e., they reflect the actual risk profiles of the insured subject. In a world where all

these three assumptions hold true, firms cannot charge unnecessarily high (unfair) premiums, because other firms would undercut them, gaining market shares and profits. At the same time, even in competitive markets, too many loading factors might force firms to charge unfair premiums, which could turn out to be too high for many potential subscribers.

The optimal insurance coverage is what emerges from a bargaining process where all the above-mentioned assumptions hold true (Phelps, 2010). It is thus possible to show that risk averse people, perfectly informed about their private risks, will choose *full coverage* (i.e., a reimbursement of all the medical expenses they will incur if they get ill) in exchange of the *fair premium* offered by perfectly informed firms working in a competitive environment. In this baseline model, markets are efficient and people get their fair deal.

Health Coverage and Insurance Markets

The baseline model is a useful benchmark. It provides a precise definition of the assumptions needed for health insurance markets to be efficient. However, it is realistic to expect that in many real world situations some of these assumptions would fail. Since the 1970s, the economic literature has gained substantial understanding on the functioning of health insurance markets when more realistic frameworks are used.

This literature has become very influential in the last decade and has set the basis for many policy interventions in the field of health systems design and health insurance regulation. In the following, the most important issues emerging from this literature are briefly explained.

Preexisting Conditions and Risk Selection

One of the most pervasive problems related to a voluntary market for health insurance comes from the simple observation that the premium should reflect the individual risk. Age-related illnesses or chronic diseases (preexisting conditions) can become very difficult to cover in an insurance market, since the premium required to insure against an almost sure event (i.e., needing some sort of health treatment) is too high. This situation can create two related types of problems (Cutler and Zeckhauser, 2000).

First, the market can fail altogether. In the most extreme cases, the probability of getting ill is so close to one that the fair premium is equal to the reimbursement. This means that the insurance contract does not exist. In practice, this failure translates into the exclusion of people with preexisting conditions from the market for health insurance (see also Section Supply Side below). In this sense, some have suggested that the choice of insurance is mainly intertemporal and that people should buy health for their lifetime (always *before* a health condition appears) instead of annually (Cochrane, 1995). However, these types of contract are not easily found in real world markets. Second, it should be noted that the insurance choice is always limited by resources availability. A poor is less likely to buy health insurance and access health care than a person with high income (e.g., Clark et al., 2013; Hsiao, 1995; Preker et al., 2007). Moreover, budget constraints are more likely to 'bite,' excluding from the market the high-risk people, which are also poor.

It is important to stress that the high risks are the people that most need access to health care and health treatments. Hence, the system fails exactly those it is supposed to serve. The problems raised by preexisting conditions and aging in health insurance markets are then particularly important and are well-recognized in most health systems around the world (see also Section Health Insurance around the Globe on this).

Asymmetric Information

The baseline model assumes that agents have perfect information about virtually everything. However, in reality one party can have more information than the other, i.e., information can be asymmetric. The literature on asymmetric information, started in the 1970s, has developed a great body of theoretical and empirical evidence. Here we define the most common typologies of asymmetric information problems commonly associated to health insurance markets.

Adverse and Advantageous Selection

In health insurance, adverse selection occurs whenever the asymmetric distribution of information causes markets to screen out the good risks, selecting only the 'bad' ones. Adverse selection is a phenomenon intrinsic to any insurance system. It can happen mainly for two reasons: the insured knows something that the insurance does not or they both have the same information but the insurance company is not allowed to use it in setting the premium, due to antidiscrimination laws or to regulatory limits to the rating system.

The problem of adverse selection was firstly identified in markets with asymmetric information on products' quality (Akerlof, 1970). Subsequently, the analysis was extended to the health sector in a very influential article that set up the basic formalization of the issue (Rothschild and Stiglitz, 1976), which proceed as follows: imagine that there are now two types of persons, one high and one low risk, but that the insurer cannot distinguish one from the other. For example, subscribers can be either smokers or nonsmokers, with the insurer unable to observe their true type. In this case, the problem is that if the insurer offers two different contracts, one for the low risk (nonsmokers) and the other for the high risks (smokers), the high risk can pretend to be low risk and get a better deal. Since the insurer cannot tell one from the other, this situation is not sustainable.

One possible solution could be to offer some form of average premium to everyone (pooled premium). However, for low risks this premium is unfair. They are thus less likely to accept the deal and some of them will exit the market. Since the remaining pool will include relatively more high risks than before, the insurance will be forced to increase further the average premium in order to balance the exits. This will force some other low risk types to turn down the offer. The process could potentially go on until only high risks remain in the market, i.e., adverse selection. This phenomenon is also known as the 'death spiral' in health insurance markets (Cutler and Zeckhauser, 1998).

Under certain conditions, the failure of pooling contracts could be overcome by offering contracts through which buyers

self-select themselves (i.e., separating equilibrium). That is, the insurer can offer a combination of premium-coverage that is the best option only for the high risk and another that is optimal only for the low risk. By picking one option or the other, subscribers reveal their true risk profile. This could potentially represent an equilibrium. It turns out that these types of contract imply offering to the low risks less than the full coverage in exchange of a fair premium (Rothschild and Stiglitz, 1976). That is, low risk profiles agree to give up part of the coverage in exchange of a fair premium, while the high risks prefer to pay a higher premium in order to be fully reimbursed. With respect to the full information scenario, the low risks would be worse off, since they pay the same but they get a lower coverage. This is the loss associated to adverse selection when the market does not fail. In addition, however, it is also possible that if the proportion of low risk buyers is higher than a certain threshold, no separating equilibrium exists either, so that only the high-risk profiles remain in the market.

The existing empirical evidence on adverse selection is contradictory (Cohen and Siegelman, 2010). According to the method and the data analyzed, some studies find a positive relation between risk profiles and insurance coverage (Sapelli and Vial, 2003; Spenkuch, 2012), others do not observe such a correlation (Cardon and Hendel, 2001; Fang et al., 2008; Finkelstein and McGarry, 2006). Evidence of separating equilibria through underprovision of insurance to low risks has also been found (e.g., Buchmueller and DiNardo, 2002).

There are different responses to the challenges posed by adverse selection. Two are worth mentioning here. First, if the insurance company can acquire the missing information after the claim has been filled, then an *ex-post* control can be imposed and defined in the contract. In this case, however, the company must be allowed to use the information about the individual claimant. This applies, for example, to smoking. Second, the regulator can introduce an individual mandate on health insurance. This is the approach taken by many countries such as the Netherlands or Switzerland and is one of the main pillars of the Obama health care reform known as the Affordable Care Act (ACA) in the US (US Congress, 2010). In this case, since all the residents are obliged to subscribe to some form of insurance, good risks are automatically included into the system and average premiums might reduce (e.g., Hackmann et al., 2013).

In recent years a literature has emerged pointing out an opposite phenomenon to adverse selection: advantageous selection (De Meza and Webb, 2001; Hemenway, 1990). Advantageous selection arises whenever those who are more risk averse both buy more insurance coverage and have lower risks. In other words, when cautious and risk averse individuals are also more likely to sign up for insurance. Advantageous selection shifts the attention from the actual individual risk profiles to their risk aversion, which is obviously not known to the insurer. From the point of view of the insurance company, however, this type of selection is profitable. Although the empirical evidence so far seems to confirm advantageous selection in the US, for example, in long-term care insurance (Finkelstein and McGarry, 2006) or in the Medigap (Fang et al., 2008), it is important to note that adverse and advantageous selection can, and probably do, coexist in these markets (Einav and Finkelstein, 2011).

Moral Hazard

Moral hazard occurs whenever people take more risks or demand more health care just because they signed up for health insurance (Arrow, 1963; Folland et al., 2006). Broadly speaking, moral hazard can arise before (ex-ante) or after (ex-post) a claim is filed. In the former case, people would reduce their preventive effort (for example, paying less attention or doing less physical activity) because they feel 'safe,' i.e., insulated from the losses they would face in case the negative event materialized. In the ex-post moral hazard, the claimants would increase their demand for health care services beyond what they would be willing to buy if they were not reimbursed. In other words, they demand excessive medical services just because they are (partially) free. Note that moral hazard is based on the assumption that the insurer cannot observe the insured's actions. This is why it is often referred to as *hidden action*.

Ex-post moral hazard is considered a serious problem for voluntary private insurance (Pauly, 1968; Zeckhauser, 1970). Indeed, when confronted with an excessive demand of reimbursements, insurance companies might raise their premiums above what is considered fair by some subscribers. Government-based health systems also suffer ex-post moral hazard, often in the form of too high demand for pharmaceuticals and medical diagnostics. Although ex-post moral hazard is a pervasive phenomenon in health insurance markets, solutions do exist and are widely applied. Since the problem originates in the free access to health care services, the solution is simply to make the patient share part of the medical costs. This is usually done through deductibles, copayments, and coinsurance, as defined above (Folland et al., 2006).

Empirically, moral hazard has been tested in one of the first large-scale randomized study in social science, the RAND Health Insurance Experiment (Brook et al., 1983; Manning et al., 1987). Between 1974 and 1982 a total of 5809 people were randomly assigned to different insurance plans: free health care, individual deductible plan (family pays 95% of costs under $150), a series of intermediate coinsurance plans (coinsurance of either 25, 50, or 95% until the threshold limit of $1000 per family). These subjects were then followed for the whole observation period. Results showed that free-care insured were more likely to go to the doctor and to be hospitalized. At the same time, health consequences were negligible. This can be seen as a strong support for the theory of moral hazard.

These results have been very influential throughout the 1990s in the health policy debate. Serious criticisms directed toward both the method and the interpretation of the results have, however, been advanced in the literature. Two such criticisms are of particular importance.

First of all, what might look like opportunistic behavior (demanding more medical care when it is freely accessible) could actually be the consequence of the income transfer from the healthy to the sick implicit in any health insurance mechanism (Nyman, 2003, 2001, 1999). In other words, one person might ask for new medical treatments not because medical care is free or cheaper, but simply because without insurance the same treatment would not be affordable. Indeed, increasing accessibility by making treatment affordable should be one of the main purposes of health insurance. Also, medical treatments are always related to personal costs that are increasing

with the complexity and the invasiveness of the intervention. In these cases, people would not ask for medical treatments if they did not actually need them. It is thus important to distinguish between different types of services. For important and expensive treatments, an increase in usage following insurance coverage might signal an improvement in accessibility to health care rather than opportunistic behavior.

A second criticism is related to health care access for preventive reasons (Ellis and Manning, 2007; Seog, 2012). Consistent with the evidence, higher copayments imply lower demand for diagnostic and preventive medical services. This means that people might refrain from seeing the doctor or run diagnostic tests if the cost is too high. Studies generally focus on the savings for the insurance from this contraction in demand and interpret this phenomenon as a reduction of moral hazard. However, for patients who have a condition, this would represent just a postponement of treatment. In general, high copayments might inhibit early detection of illness. Since typically it is cheaper and safer to treat conditions earlier rather than later, what might appear as a saving might turn out to be an increase in the overall expenditure. For example, analyzing 172 Medicare plans in the US, 18 of which raised copayments for ambulatory care during the observation period, a study found an average reduction (between 2001 and 2006) in the number of ambulatory visits for the group whose copayment increased (Trivedi et al., 2010). This is consistent with moral hazard. On the other hand, for the same group the hospital admissions increased by 2.2%. Overall, although copayment saved $7150 per capita in reduced demand for ambulatory care, it increased by $24 000 the expenditure for inpatient care.

Overall, moral hazard is unavoidable in health insurance. It affects both private and public systems. In theory, the problem can be ameliorated by using deductibles and copayments. However, caution should be taken in interpreting any 'excess' demand as a sign of opportunistic behavior, possibly avoiding overreactions and extreme policy implications.

Supply Side

The main assumption for the supply side in the baseline model is that firms compete on prices. In other words, they try to get people to subscribe to their policies by offering the best price for any given coverage. This assumption is particularly problematic in reality and often requires some sort of government intervention at various levels.

The first issue to be considered is risk selection, also known in the economic literature as *cream skimming*: the selection by the insurance providers of those consumers expected to be more profitable given their risk profiles (Barros, 2003; Ellis, 1998). Within the same premium-risk group, profitability is inversely related to the risk profile of the subscribers: good risks are profitable and firms will try to attract them. Even when they are not allowed to directly deny access to insurance to the bad risks, for example, because they are obliged by law to accept subscribers independently from their risk profile, they still can set up contracts and offer services that are typically more appealing for the good risk profiles. Competition in this case can be problematic to manage. One solution is risk adjustment (Shen and Ellis, 2002; Van de ven and Ellis, 2000). Information can be used to subsidize firms for each high risk in the pool of the enrollees. Hence, pools with proportionally more high risks will receive more subsidies. Subsidization can come from either the government or other firms with advantageous risk profiles among their pool. If correctly set, these subsidies can significantly reduce the incentive for risk selection.

A second issue arising from competitive health insurance markets is related to the presence of administrative costs and other loading factors. In these cases, firms would need to increase premiums above the fair level in order to recover the additional costs. This would alter significantly the picture emerging from the baseline model (Einav and Finkelstein, 2011). Administrative costs in competitive markets imply a duplication of resources and procedures, which reduces the efficiency of a free market health insurance system.

Competition might even be difficult to achieve. The literature in industrial economics is full of examples of markets where firms either do not compete with each other because they can collude or do not find it profitable to start price wars (Martin, 1994; Tirole, 1988). Much depends on how easily new and small firms could enter the market and gain market shares by offering low premiums. For example, the presence of switching costs, i.e., fixed and psychological costs people have to pay when they change insurer, do indeed represent an obstacle for competition in health insurance markets (Farrell and Klemperer, 2007; Frank and Lamiraud, 2009).

Health Insurance around the Globe

Both the theory and the empirical observations have clarified that universal health coverage, i.e., universal access to health care, cannot be achieved through market mechanisms only. Information and economic problems are too pervasive to the system. Government interventions, whether in the form of regulation, redistribution, or direct provision of insurance and health care, characterize the organization of health systems everywhere around the world.

Countries generally have developed different and complex systems to provide health care to their citizens. Health care systems are often classified in many different ways depending on the types and numbers of factors researchers might find relevant to consider (Beckfield et al., 2013). A health system, however, is determined by the interaction of different actors, such as insurers, patients, and medical providers. Hence, a precise taxonomy of health systems goes beyond the purpose of the present article, which focuses on insurance only. In this sense, a common classification of health systems from the point of view of the insurance dates back to the early 1970s (Anderson, 1972) and identifies three general approaches: the Bismarck model, the Beveridge model, and the voluntary/private insurance model.

The *voluntary health insurance* model is essentially the one described so far, where people decide whether to buy health insurance and companies supply a variety of contracts suited for all the different risk profiles. It thus sees health insurance as a good to be exchanged in the market, as any other good. To the extent that universal health coverage is a concern within a country, government interventions in this model usually take the form of the introduction of some form of public health

Table 1 Bismarck and Beveridge approaches to health insurance

insurance for those high risks for which the system might fail. The typical examples in this sense are Medicare (public insurance for those over 65) and Medicaid (public health insurance for the poor) programs in the US. In addition, more recent reforms, such as the ACA, have tried to tackle adverse selection and the exclusion of preexisting conditions by imposing an individual mandate for health insurance for every US citizen and by requiring insurance providers to compulsorily accept high risks (Austin and Wetle, 2012).

Interestingly, politicians have grasped the weaknesses implicit in the voluntary health insurance mechanisms long before the economic theory could formally explain them. In particular, the two most common names quoted when describing the alternative health systems are Bismarck and Beveridge (Lassey et al., 1997).

Otto von Bismarck (1815–1898), a Prussian statesman and Chancellor, first understood the importance of welfare programs for maintaining order and status by gaining the support of parts of the working class. Often described as a conservative and nationalistic politician, he introduced, with the support of the German industry, old age pensions, unemployment insurance, and health insurance. In *Bismarck* model, health coverage is distributed through employers related to Social Health Insurances (SHIs) (Burau and Blank, 2006). Hence, health coverage can change substantially according to the position in the labor market. SHIs are financed through payroll contributions levied on employers and employees and are in competition with each other. The private sector can thus have an important role within the system, although coordination among different players is a key for success. In particular, competition is usually heavily regulated and the government can keep a strong redistributive role. In general, workers and patients can maintain the power to choose among different insurance providers.

William Beveridge (1879–1963) was a British economist and politician who, in 1942, wrote a very influential report on welfare and unemployment. The so-called 'Beveridge report' set the scene for the establishment of the National Health Services under the Labor government of Clement Atlee in 1945. According to Beveridge, health and social insurance in general should be financed through a contribution by all working people in the country, something that now is referred to as general taxation. Originally, in these systems health care was meant to be provided entirely by public hospitals. Indeed, sometimes in the international literature the Beveridge model is viewed in this purest version. However, as clarified by the *quasi-market* reforms introduced by Margaret Thatcher at the end of the 1980s, Beveridge systems can separate the purchasing authority, which must remain the taxed-based public insurance, from the providers, which can be either private or public.

In Table 1 the main characteristics of the Bismarck and Beveridge models are summarized. Examples of countries are provided. Note that although in principle the distinction between the two types of systems is clear, in most Bismarckian countries the government actually intervenes in various ways to assure universal health coverage and sometimes to fix directly the reimbursement rates of medical services. Indeed, according to some scholars, the two systems are meant to converge in many different dimensions (e.g., Stevens, 2009).

Health Interventions, Community-based

Abstract

This article describes the optimum mix of education, organization, and regulation needed for success in community-based programs for changing health habits underlying preventable chronic disease. Historically, success occurred only when social cognitive theory's principles were embedded within a social marketing framework. A paradigm shift toward greater effects and broader global dissemination could occur were digital health methods incorporated into the current model, particularly if supportive regulatory public health policy were also present.

Recent decades of comprehensive multilevel community-based health interventions have yielded major successes in health outcomes and, in some instances, transfer of novel health education technologies to the health, media, and education infrastructures of communities. The likelihood for success benefited from leadership involving activism, advocacy, and coalition building; and use of social marketing in timing, intensity, frequency, and duration of the messages delivered. Educational content relying on social cognitive theory embedded in a mass communication vehicle produces satisfactory change, even for ordinarily resistant behaviors, such as eating habits and use of alcohol or tobacco. Such a model leads to empowerment, an increase in social capital, and a 'healthy' community, which has achieved 'community efficacy.' The model has had widespread international diffusion and has changed health policies toward primary prevention in many nations. However, there are challenging future obstacles to its adoption, including poverty, social inequity, environmental and educational deficiencies, and, unfortunately, lack of recognition of the excellent scientific basis for the model's efficacy. Achieving future success will therefore require: (1) a conviction that cost-effective technologies for community-based health interventions are ready for adoption and dissemination; (2) policy changes based on a 'prevention pays' philosophy; and (3) a wise allocation of intervention resources, a step needed to overcome barriers and avoid widening existing gaps in health status among population subgroups and among nations varying in their economic development.

This article considers theories and methods underlying successful community-based health interventions, emphasizing six exemplars. Three exemplars focused on cardiovascular disease (CVD) prevention and relied heavily on modern means of mass communication and social marketing, relatively low-cost approaches with the potential to reach and change lifestyle behaviors of entire populations, in contrast to traditional individual or group counseling. One exemplar, studying alcohol-involved trauma, used community organizing for adherence to existing laws, rather than public education for behavior change. Another relied primarily on changes in a city ordinance on a harmful food ingredient, initiated by its public health department. In this instance, the public had become aware of the health issue, largely from a few years of local and national media attention. The sixth exemplar, the nationwide tobacco control program, spanning 1964 to the present, represents how a long-term effort involving multiple communities and states led to a national program, thus demonstrating *national* success from combining educational and regulatory measures used in the five other exemplars. The article also describes barriers to change and lessons learned for future extensions of such endeavors, including the need for a paradigm shift in the methods of education itself.

By definition, a community-based program is organized locally, achieving its goals through the community's institutions and communication networks, often assisted by public health and academic agencies extrinsic to the community. A community is defined here as a residential area with legally defined geographic boundaries, where a governmental system regulates certain local aspects of schools, businesses, transportation, policing, and recreational activities. A community is ordinarily last in a nation's regulatory chain, where education must ultimately occur, although for rural areas in the US, the *county* becomes the governing agent for many services.

The relevance and intellectual contexts of community-based health education are addressed through these questions: (1) What is the rationale for community-wide interventions rather than in more limited locales such as clinics, hospitals, worksites, or schools? (2) What theories, methods, and resources underlie success? (3) How does a community become committed to a novel health education campaign? (4) How can barriers to success be overcome in such interventions? (5) What roles do community activism, laws, and regulations play? (6) What is the future of community-based health education?

Rationale

Health education in schools, worksites, and clinics have a long history of individual success, but synergistic interactive effects can occur when they are embedded in a total community campaign that adds inherently cost-effective mass media and environmental change (Farquhar et al., 1991; Schooler et al., 1997). Culturally induced lifestyle changes, so powerfully influenced by custom and by the media in developed countries, cannot be countered effectively through simple means. Community-wide approaches fit the public health model because the traditional medical model cannot prevent most chronic disease, reach the entire population in need, or modify the environmental and social factors that underlie many

harmful health habits. The community provides influence through locally produced electronic and print mass media, when available, and through worksites, schools, medical and hospital settings, families, and all social networks and social gatherings. It offers opportunities for health-promoting regulations, such as providing opportunities for physical activity for all, school fitness classes, healthful school lunches, alcohol sales limits, and preventing tobacco product marketing to children (*see* Health Promotion in Schools).

Studies at the Stanford Prevention Research Center (SPRC) have shown that only multiple influences produce meaningful changes in the dietary, exercise, or tobacco-use behavior of adults, adolescents, and children. For adolescents, always resistant to health behavior change, the following influenced success: parent and teacher roles; school environments; amount and quality of school-based education on tobacco, fitness, and nutrition; peer influence; and amount and quality of community-wide health education (Perry, 2000). Also, certain personal characteristics were influential, for example, self-efficacy toward one's behavior-change abilities (Fortmann et al., 1995).

Theoretical Formulations

Community-based health education done by SPRC and by some analogous projects has been guided by three major theoretical and management models (Flora et al., 1989; Farquhar et al., 1991).

1. The community organization framework provides methods of identifying the health problem (and resources needed or available), mobilizing the community's opinion leaders and organizations, gaining populace support, forming coalitions, launching and maintaining education programs, achieving regulatory changes, and empowering communities to reach and maintain their goals (Green and Kreuter, 2005).
2. Social marketing provides designs and sequences of messages for population subgroups based on health needs, cultural attributes, social networks, media habits, and readiness for change (Flora et al., 1997).
3. The mass communication–behavior-change model describes theories underlying educational content, such as social cognitive theory (Bandura, 1986), and media-based methods of reaching and influencing the total population in multiple ways (*see* Self-Efficacy and Health).

Intervention Principles, Methods, and Resources Needed for Success

Acceptance

Both relevant organizations and political and opinion leaders must be recruited into a coalition that sanctions any novel health education project. Many projects are initiated by public health and academic leaders extrinsic to the community, but require full acceptance and cooperation within a coalition of the *community's* leaders and organizations. This coalition must identify the health problem (needs assessment), provide a resource inventory, obtain populace support, and plan the intervention, with support derived from both internal and extrinsic sources.

Comprehensive

Interventions must go beyond attempting to change knowledge, the usual educational goal, by providing training in behavior-change skills. They must also go well beyond the individual, enlisting multiple community organizations, including local media outlets, in campaigns for change and seeking changes in the social environment and in regulations that promote access to the facilities and resources needed for healthful practices. Multiple communication channels are needed to reach different audiences, recognizing their preferences, stage of knowledge, and readiness for change. A comprehensive intervention should involve local media organizations, schools, worksites, churches, and sport, recreation, and health facilities. These organizations and others can serve as education conduits, with the community's electronic and print mass-media organizations assisting in message design and delivery. The Internet, mobile, and other digital health devices provide new channels, whose community education role is as yet poorly defined. Interactive computer learning can be designed for large groups – an emerging mass-media variant. The advent of these digital health technologies has now furnished the potential for new and exciting intervention methods (King et al., 2008), which have not yet been studied in a comprehensive multilevel community-based intervention setting.

Variety, Integration, and Timing

Comprehensiveness requires variety. For example, in tobacco control components of Stanford's CVD campaigns, local medical clinics, dental offices, pharmacies, libraries, and voluntary health associations distributed a low-cost skills-training Quit Kit; a local smoking cessation class appeared on television; many newspaper articles and columns were printed; local businesses supported costs of a smoking cessation contest; and all newspapers and electronic media 'cross-advertised' activities designed for mass audiences. Success also requires an appropriate mix and sequence of programs delivered through varied channels. This integration, with goals set in advance and goal changes based on early results, is analogous to a commercial marketing campaign, hence the term 'social marketing.' Timing dictates that differently themed 'mini-campaigns,' often of 3–6 months duration, be used to create novelty in an overall campaign of more than 2 years duration, which is often a time for evaluation of major results.

Message Design and Audience Segmentation

Social marketing requires message tailoring for each subgroup's needs and preferences, recognizing cultural differences, learning styles, and preferred learning sites. Message sequencing should increase awareness, then, increase knowledge, and last, increase motivation and provide training in the skills needed for adoption and maintenance of a new behavior (Bandura, 1986). Electronic media can carry out the sequence's

first two parts and stimulate use of the more information-dense print media of newspapers and booklets, which are inherently more effective in skills training than are electronic media (Flora et al., 1997), although newer digital health technologies can now excel in skills training (King et al., 2008). Messages must be clear, focused, and salient. Salience requires broad-reaching media, arousing interest, and awareness – topics must break through passive indifference engendered by the information overload of many societies and become 'on the public agenda.' Given the large advertising budgets of today's mass media, health agencies' messages must be of sufficient production quality to compete for the public's attention (Farquhar et al., 1990).

The Message Must Be Effective

Behavioral research confirms the rather self-evident rule that 'learning by doing' is more effective than 'learning from observing' (modeling a behavior), and both are more effective than an 'information-only' approach that changes knowledge alone. These principles are contained in Bandura's social cognitive theory, which posits that guided practice in a new behavior can lead to increased self-efficacy and greater behavior change (Bandura, 1986). Thus, 'knowledge-only' campaigns have been found less effective than those that apply Bandura's recommendations (*see* Self-Efficacy and Health).

Intervention Dose

The dose needed depends on many factors: lesser amounts for smaller communities, at earlier stages in a country's adoption of a 'health innovation,' and when advocated behavior changes are reasonably simple (such as mammography, hypertension screening, and immunization campaigns). Clearly, more complex changes are needed in individuals and in society's norms to alter eating or exercise patterns or to control tobacco use. Complexity in respect to nutrition arises from many sources, including long-standing cultural beliefs and practices; entrenched agricultural methods, including those of food production and retailing; advertising of 'unhealthful' foods; and the advent of widespread fast-food chains dominated by commercial interests unresponsive to local demands and needs. Few projects have measured intervention dose with any precision. One excellent method, used in Stanford's Five-City Project (FCP), records the total number and duration of messages distributed over all channels for a defined time period, with message quality estimated from formative evaluation (Farquhar et al., 1990). However, were this method widely adopted, public health practice would benefit greatly.

Role of Activism and Advocacy

Successful community-based health education requires effective leaders, community activists with the courage and charisma to advocate health innovations. Waves of advocacy filtering down from international, national, state, or provincial sources can wash up on the shore of an inert community to provide a local activist leader with the popular support to 'fight city hall' or other entrenched bureaucrats who defend the status quo. Tobacco control in Australia and the US provide examples. National and state advocacy groups with access to mass media created a strong mass movement for change, allowing advocates to enlist popular support for local tobacco control measures (Levy et al., 2012) – (see exemplar six). In both California and Australia's State of Victoria this popular support led to statewide increases in tobacco taxes, with some retained for education against tobacco, a measure that had been resisted by state legislators who had long been influenced by tobacco lobbyists – an example of community activism filtering up the political chain to provide pressure at a higher political level (Catalonia Declaration, 1996; Rogers, 2010).

Role of Policy, Laws, and Regulations

Local actions can affect alcohol and tobacco sales and create environments that improve nutrition and enhance physical activity. However, national, state, or provincial actions can magnify local policy, laws, and regulations, and education efforts on topics, such as tobacco taxation, automobile seat belt laws, food and drug safety, school nutrition, school physical activity policies, and (in the United States) laws on firearms. As described in Section Community Projects in Other Health Topics on tobacco control, widespread popular attitude changes in numerous communities can also affect the political process at the state or federal level.

History of Comprehensive Community-based Health Education for CVD Prevention

The history of CVD risk factor trials since the 1970s is restricted largely to 13 formal research projects (Schooler et al., 1997). They involved entire populations of at least one education community, compared with at least one control community. Three of the following five exemplars are drawn from these 13 projects. Dissemination into practical applications of community organizing and mass communication technologies occurred throughout many parts of the world, derived in part from these research projects.

The First Two Exemplars: The First Decade

The first and second exemplars, Stanford Three-community Study (TCS), in three small agricultural marketing towns in California (total population 45 000), and the North Karelia Study (NKS), in two adjoining predominately rural Finnish counties (North Karelia population about 180 000), each began in 1972. TCS, the first Stanford project, was carried out from 1972 to 1975 in both English and Spanish, comparing effects of mass media alone in one community and mass media plus 10-session risk reduction classes for high-risk adults in a second, with a third as a control (Schooler et al., 1997). Groups exposed to varied education amounts showed a dose–response change in knowledge, smoking, blood pressure, and blood cholesterol, with a proportionately larger effect in the Spanish-speaking residents than in the Anglo majority. A composite CVD risk reduction of about 23% and 30% occurred in the mass media only and mass media plus

classroom conditions, respectively. Thus, a relatively modest amount of mass media (about 30 television and radio 'spots,' weekly newspaper columns on heart health, and 4 separate mass mailings of booklets) was sufficient to change the population's body weight, cholesterol and blood pressure levels, and smoking prevalence. The education followed Bandura's principles but adapted to the mass media (as was also the case with exemplars two and three).

NKS evaluated two, matched, rural Finnish counties containing many villages with farming and lumbering as the main occupations. North Karelia received an education campaign beginning in 1972, continuing for over 20 years. After 5 years, CVD risk factor changes comparable to the TCS and significant net reductions in CVD events occurred (Schooler et al., 1997). Continued intervention, assisted by Finland's excellent public health system, showed progressively larger decreases in coronary heart disease and stroke mortality, and after 20 years, a reduction in North Karelian male lung cancer mortality related to successful smoking cessation (Puska, 1995a). This study employed extensive community organizing, resulting in strong partnerships with residents and their organizations. The NKS influence on its country's policies was unparalleled among the CVD projects, providing its most important lesson – that a well-executed project led by respected scientists can move an *entire* country. As examples, Finland's food and agricultural industries made large changes: fertilizers were supplemented with selenium (a substance needed for health, but low in Finland's soil), milk pricing was changed (based on protein instead of fat content), some dairy farms were replaced with berry farms, a new canola industry replaced jobs lost in dairying, and increased production of low-saturated fat foods occurred (Puska, 1995b).

In 1972, population-wide nutrition change and smoking cessation interventions were an innovation internationally, which may partly explain the success of these two pioneering programs (TCS and NKS).

Early International Diffusion, 1977–83

Studies in small communities patterned after the TCS were done in Italy, Australia, Switzerland, and South Africa, all with significant risk factor changes, adding evidence for the effectiveness of the TCS CVD prevention model (Farquhar et al., 1991; Schooler et al., 1997).

The Second and Third Decades: Projects Begun in the 1980s and 1990s

The third exemplar is the Stanford FCP (USA). Its intervention phase from 1980 to 1986 extended TCS methods to larger populations (total population of about 360 000) with multifactor CVD prevention directed at two northern California cities. There were three control cities (Farquhar et al., 1990). It differed from TCS in greater use of community organizing and collaboration with the communities' health, media, and education organizations in planning and implementing programs. It was similar in generous use of mass media, both print and electronic (63% television and 36% print). It was unique in measuring the total dose of education (about 5 h per year and about 100 episodes of exposure per year to all forms of media and classroom education) (Farquhar et al., 1990).

FCP's initial year of television messages (defined as 'high reach/low involvement') stimulated the public's print media use, which supplied more effective skills training than television (Flora et al., 1997). Results were comparable with the TCS (about a 15% fall in composite risk of CVD), with a major impact on blood pressure and smoking (Farquhar et al., 1990). Health bureaucracies, usually timid, should gain courage from the FCP's 'David and Goliath' demonstration that only 3 h per year of high-quality television health education can counteract the public's exposure to about 100 h per year of television advertising devoted to unhealthy nutrition. Although all preceding CVD studies showed effects in small towns and/or rural districts, FCP showed benefit in cities (with populations as high as 100 000). Also, these effects occurred despite the advent (at least in the State of California) in the 1980s of dual working families and increasing public use of fast food, factors that made achieving nutrition behavior change more difficult.

FCP's modest resources and greater effects, as compared with some comparable projects, support the benefits of the skills-training aspects of Bandura's social cognitive theory and in extensive use of social marketing. Perhaps the most practical lesson to policy makers is that adult residents saved 30 times more money from their decreased cigarette purchases ($120 per adult per year) than the cost of the campaign ($4 per adult per year) – savings retained by the community. Lastly, the communities adopted FCP's technologies, later applying them to seat belt promotion, violence prevention, and adolescent pregnancy prevention.

Other successful CVD projects, both large and small, occurred in these decades in the US, Sweden, Denmark, Canada, the Czech Republic, and China. One notable study, the Minnesota Heart Health Project, developed many innovative methods, including pioneering the use of a community-wide smoking cessation contest (Luepker et al., 1994) and pioneering health education involving multiple schools in a community (Perry, 2000). Also, World Health Organization-sponsored projects began in about 23 other countries (Schooler et al., 1997). In many instances, they borrowed heavily from the experiences of the three exemplars, often receiving training from either Stanford or North Karelia groups.

Community Projects in Other Health Topics

HIV/AIDS trials were launched in the 1990s, using many methods developed in the earlier CVD trials (Coates et al., 2008), giving beginning evidence of the model's effectiveness in developing countries. Interventions on alcohol, mammography, immunization, family planning, mobile X-ray screening, tobacco control, motor vehicle injuries, and, recently, obesity control are prominent examples of other community-based projects, but with fewer well-controlled studies than in CVD. One of these, Preventing Alcohol Trauma (PAT), is the fourth exemplar. This 5-year study of three US communities showed a 10% decrease in alcohol-related traffic injuries and a 50% decrease in adolescent alcohol use (Holder et al., 1997). Coalition building and organizational behavior change among the

police, alcohol sales outlets, and alcohol servers were the main interventions. The public responded to a fear, instilled through publicity, of penalties from greater enforcement of existing laws on underage alcohol purchases or drinking and driving. Therefore, in contrast to the three CVD exemplars, PAT showed that major public education is not needed for large public behavior changes. PAT estimated a cost saving of $2.88 for every dollar invested, a number close to that found in many worksite health promotion (WHP) studies. PAT found their communities had the required infrastructure for the campaigns, requiring only training provided by one indigenous community coordinator, a part-time clerk, an imaginative plan, and the will to proceed.

TCS, the first, and PAT, the fourth exemplar, are opposites: TCS had a maximum of mass-media education and a minimum of organizing, whereas PAT the opposite. Thus, either model works, but to change complex behaviors, one needs sophisticated behavior-change methods, such as those adapted from Bandura (*see* Self-Efficacy and Health) and embedded within a social marketing framework (Flora et al., 1989). If fear of arrest for breaking existing laws on alcohol use suffices to change personal drinking and driving habits, then the education process is simpler.

The fifth exemplar, done recently in New York City, demonstrated that a City's Public Health Department ordinance alone was very successful in eliminating trans fats, which raise cholesterol levels, from the city's restaurants and food markets, whereas a voluntary ban did not. However, an additional feature of this success is that considerable public support existed, engendered by a few years of public attention to the health impact of these fats (Angell et al., 2009). The lesson fits with the aforementioned successes in the national antitobacco campaign's use of laws and regulations in fighting a public health menace.

How Community and State Actions Can Change National Policy

The sixth exemplar, the national tobacco control policy, formally launched in 1964 by the US Surgeon General's first report on Smoking and Health (Smoking and Health, PHS publication 1103, 1964), was assisted throughout by actions at community and state levels. It is often heralded as a singular public health success, appropriately demonstrating the impetus for policy change *filtering up* from an informed, and now concerned, electorate, a process termed 'denormalization' of tobacco use. This emerges as an example of 'multiple communities' banding together, producing a mass effect. The national media, including of course its local media outlets, was responsible for some of the public's transformation, as were the excise tax policies of the States of California and Massachusetts, which acted as harbingers of changes yet to come (Chaloupka et al., 2002). Accordingly, the impetus for public health policy changes at all government levels will increase as economic burdens from preventable chronic disease become clearer. For example, major reductions in health-care costs are predicted from smoking cessation trends in the State of California (Max et al., 2012).

Lessons Lead to a 'Master Plan'

A five-step approach emerges, particularly from the CVD prevention trials, although the educational and organizational elements pertain in principle to all community-based education programs.

1. Define the problem. Does the community need a health education campaign? A decision can emanate from national, state, or local survey data.
2. Organize the community, creating a campaign that includes education, continued organizing, training of community organizations, empowerment of the public and the community's organizations, and future maintenance of programs developed during an initial phase of about 2 years.
3. Implement an intervention, delivering 3–5 h of education exposure per year for 2 years, using initially about 50% television to arouse interest, followed by about 25% from more specific print media (emphasizing newspapers, if available), and 25% from community events and programs (such as health fairs, contests, and classes). Future integration of digital health methods will be needed, following needed research.
4. Institutionalize programs. The community becomes a demonstration project, with its 'empowered' organizations functioning as health promotion resource centers for a wider region.
5. Use the new community resources and its residents' potential power to advocate for local, regional, and national governmental regulations and laws that will increase local intervention effects and extend them beyond the community.

Any individual or organization that wishes to engage in community-based health education should gain courage from the words of Margaret Mead, as quoted in the closing passage of the Catalonia Declaration (1996: p. 75), "Never doubt the capacity of a few dedicated individuals to change the world, in fact, it is the only way it ever has."

Barriers and Challenges

A healthy city has been defined by the absence of crime, crowding, and poverty and by the presence of educated residents and enlightened (and trained) organizations. Together these lead to a community empowered to solve its social problems (i.e., to increase its social capital) (Travers, 1997).

Considering barriers, MacIntyre (2000) found Glasgow's environmental factors to be major barriers to healthful exercise behavior. Certain macroeconomic factors inherent in globalization, such as capital flight and increased wealth and income gaps, have been described as barriers to planned change (Bezruchka, 2000; Cahill, 1983). All such barriers threaten community stability, inhibiting greatly the success of health promotion attempts. However, wise compensatory resource allocation can overcome many barriers, as was shown in the Hispanic minority of the TCS. Therefore, the challenge for the future is: Responsibility for success in community-based health interventions lies with the interventionist, not with the

community's residents! A major potential barrier is omnipresent given the diversity of cultures and levels of economic development worldwide. However, some assurance of commonality of responsiveness is present given the success of some HIV/AIDS programs in developing countries that have used media and organizational approaches common to some of the most successful CVD prevention programs (Coates et al., 2008).

New Opportunities for Greater Cost-Effectiveness

Although, satisfactory cost-effectiveness has been achieved in a few carefully executed comprehensive, multilevel CVD prevention trials, their full potential is greater. Examples: (1) Although, worksite health promotion (WHP) in large US companies has achieved over a 3/1 return on investment in health-care cost reduction (Baicker et al., 2009), WHP has rarely been applied to small worksites, which predominate worldwide, nor has a community-wide education campaign ever targeted *all* the community's worksites; (2) Similarly, school-based health education has never been done for multiple sequential years in all the community's schools during a community-wide health education campaign; (3) Social marketing has rarely been applied well; and, lastly (4) Digital health technologies, including their recent applications (King et al., 2008), have never been embedded within a comprehensive community-based campaign. Topol (2012) persuasively outlines some of digital health's promise – which forecasts a paradigm shift in community-based health education.

Conclusions

Recent decades of the comprehensive, multilevel community-based health education approach strongly support that, at relatively low cost, achieving transfer of public education technologies to a community's infrastructure (public health, media, schools, etc.) can be achieved, resulting in significant changes in health habits of populations. Although most studies derive from small communities, recent successes in New York City, a city of >8 million population (two exemplars examined populations of >100 000), suggest that the model also works in large populations (Schooler et al., 1997). Organizing and educating communities requires advocacy, activism, coalition building, and leadership; success is enhanced by regulatory change. Theory matters: when the population gains self-efficacy through education, the result – community efficacy – enhances capacity to change institutional policy and practice, thus maintaining community change. A paradigm shift toward greater effects and broader global dissemination is an exciting prospect were digital health methods added to the existing model. Science cannot serve society if its evidence for educational benefit is ignored. This is not a new concept. As written over 2000 years ago, "If a virtuous and learned scholar aims to influence the people as a whole, one must first educate the people" (Legge, 1983).

Health Literacy

Abstract

The health literacy field has evolved since the 1970s. It is associated to empowerment and refers to the capacities of people to meet the complex demands of health in a modern society. Regarding health literacy as a social determinant for health, common grounds are established to define the term; measure the concept; and apply it in research, policy, and practice. Growing evidence shows that limited health literacy is a public health challenge, which can be targeted through people-centered, cross-disciplinary, and intersectorial approaches.

The term 'health literacy' was introduced in the 1970s in relation to health education and social policy (Simonds, 1974). Since the 1990s the concept has received increasingly attention as part of the capacities of people to meet the complex demands of health in a modern society (Kickbusch and Maag, 2008). Ever since, the composite notion of health literacy has been scrutinized in terms of how to define and conceptualize it; how to measure it; and how to apply it in research, policy, and practice.

Defining Health Literacy

Health literacy is linked to literacy entailing people's knowledge, motivation and competencies to access, understand, appraise, and apply information to form judgment and take decisions in everyday life in terms of health care, disease prevention, and health promotion to maintain and improve quality of life (Sorensen et al., 2012). As such it is "a shared function of social and individual factors, which emerges from the interaction of the skills of individuals and the demands of social systems" (Nielsen-Bohlman et al., 2004). In turn, a distinction can be made toward public health literacy, which refers to "the degree to which individuals and groups can obtain process, understand, evaluate, and act upon information needed to make public health decisions that benefit the community" (Freedman et al., 2009). Whereas several definitions exist, there is a common understanding that health literacy represents the cognitive and social skills, which determine the motivation and ability of individuals to gain access to, understand, and use information in ways, which promote and maintain good health (Nutbeam, 1998). In addition, the importance of shaping health literate-friendly services and systems has been highlighted to enhance a better interaction between users and health professionals to optimize people-centered care (Brach et al., 2012).

Conceptualizing Health Literacy

The European Health Literacy Consortium (Sorensen et al., 2012) developed a conceptual framework to illustrate how health literacy can be understood as a social determinant for health. It focuses on developing health literacy through being

able to access and obtain information; to understand information; to appraise and evaluate information; as well as applying information in all forms when being ill, when trying to avoid risks and when trying to stay healthy during course of life. Health literacy is influenced by personal, situational, and broader societal and environmental factors as outlined in the Ottawa charter (WHO Regional Office for Europe, 1986) and elaborated on by the Commission on Social Determinants of Health (Commission on Social Determinants of Health, 2008). In turn, it is illustrated how health literacy has an impact on health service use (Paasche-Orlow et al., 2005), health behavior (Paasche-Orlow and Wolf, 2007), active participation in society as well as for socioeconomic sustainability (Kickbusch, 2007). The conceptual model takes into account the individual as well as the system perspective, hence recognizing that health literacy relates to the individual capacity to make sound health decisions in the context of everyday life – at home, in the community, at the workplace, in the health care system, in the market place, and in the political arena (Kickbusch, 2008) and health literacy is closely associated to the design of organizations and systems and how they are managed in order to respond to the needs and demands of people (Brach et al., 2012; Parker and Ratzan, 2010).

Previously, widespread health literacy research has been conducted, which was grounded in educational theory based on Nutbeam's three qualities of health literacy: functional health literacy, interactive health literacy, and critical health literacy (Nutbeam, 2000). Yet, recent research suggests that health literacy encompasses even more distinct attributes associated to feeling understood and supported by health care providers, having sufficient information to manage own health, being able to actively managing one's own health, social support for health, appraisal of health information, active engagement with health care providers, navigating the health care system, ability to find good health information and understanding health information well enough to know what to do (Osborne et al., 2013).

Measuring Health Literacy

Numerous tools have been developed over the course of the past 20 years in an effort to measure health literacy in various contexts. Some of these tools were developed as screening tests and others were developed as more comprehensive assessments. Accurate measurement is a critical component of success to identify topics and populations most in need of support, to help tailor interventions, and to provide metrics to evaluate progress (McCormack et al., 2013). The plethora of health literacy measures vary in the dimensions they measure, their mode of administration, the time and resources needed to use them, and level of psychometric rigor (Haun et al., in press). The most well-known measurements include the Rapid Estimate of Adult Literacy in Medicine (Davis et al., 1991, 1993), the Test of Functional Health Literacy (Parker et al., 1995), and the Newest Vital Sign (Weiss et al., 2005). As they are often used in clinical settings, these tools are necessarily short, quick, and easy to use. Other tools aim at measuring a broader concept of health literacy, with a view to provide an in-depth assessment of the dimensions of health literacy, or to explore its relationships with social determinants, health behavior, health status, or healthy service use such as the Critical Health Competence Test (Steckelberg et al., 2009), the European Health Literacy Questionnaire (Sorensen et al., 2013), and the Health Literacy Questionnaire (Osborne et al., 2013).

During the last two decades, the focus of the health literacy measurements has changed considerably. Previously, tools were predominantly designed to measure functional health literacy in clinical settings such as, understanding medical terms (R.M. Parker et al., 1995), whereas later measurements have strived to encompass health literacy as a multidimensional term focusing on a variety of aspects related to health literacy (Osborne et al., 2013; Sorensen et al., 2013). So far, more than 50 tools measuring health literacy have been identified in a recent inventory and more are under development. With the wide range of tools emerging, it is advisable to evaluate the measurements for a conceptual and practical match, when choosing a health literacy instrument for research and screening (Haun et al., in press).

Health Literacy: A Contemporary Public Health Challenge

Health literacy studies across the world has shown limited health literacy to be a risk factor in modern societies (Barber et al., 2009; HLS-EU Consortium, 2012; Nielsen-Bohlman et al., 2004). The growing evidence reveals that limited health literacy is a risk, not only for vulnerable groups such as elderly, the less educated and, among people with low socioeconomic status, but also in the general population per se, when levels of limited health literacy are up to 60%. In this perspective, health literacy can be regarded a contemporary public health challenge that needs to be addressed to ensure a more appropriate use of resources and a better health for all (HLS-EU Consortium, 2012; Kickbusch et al., 2013). Several governments have, therefore, developed strategies to advance health literacy at national levels. The United States has launched a national action plan to improve health literacy (U.S. Department of Health and Human Services., 2010); Canada has opted for an intersectoral approach to improve health literacy for Canadians; in Scotland a national action plan is under development (The Scottish Government, n.d.); and in Wales, the advancement of health literacy is associated to the efforts of overcoming inequalities (Puntoni, 2012). Austria has adopted the investment in health literacy as one of the 10 national goals (Bundesministerium für Gesundheit, 2013). In Australia, a health literacy response framework is being developed that provides tools for a whole-societal approach to build the capacity of citizens as well as of staff involved in organization of services and decision-makers in strategic planning (Osborne, n.d.). Notably, also the supranational organizations such as the European Commission and the World Health Organization have included health literacy as priority areas in their strategies (European Commission, 2007; World Health Organisation's European Office, 2012).

Characteristics of the Evolving Health Literacy Field

While health literacy is gaining more and more attention on the global agenda, the health literacy field itself is maturing. Whereas health literacy in the 1990s was promoted by individual stakeholders believing in its value for health care, disease prevention, and health promotion, the amount of stakeholders in the field has now reached a critical mass that allows for the organization of national and regional conferences as well as development of national, regional, and international networks. With these newly developed platforms for knowledge exchange, it has been possible to share ideas and evidence across the world regions. In the beginning of the century, the published peer-reviewed articles on health literacy could be counted in hundreds, yet within a few years it has raised exponentially to be counted in thousands. Due to the rapid developments and vast amount of information; the role of health professionals as knowledge brokers are as equally important as using and boosting the potential of health literacy embedded in the population (Sorensen, 2013). The advanced conceptualization of health literacy invites professionals from many different disciplines to incorporate health literacy as a priority area into their specific field of work. As a result, the notion of health literacy is increasingly being specified according to the specific topic or target group it involves, e.g., diabetes health literacy, mental health literacy, patient health literacy, aids literacy, health insurance literacy, etc.

Investing in Health Literacy

Nutbeam highlights that the solutions to the health literacy gap will differ whether health literacy is regarded a risk or an asset (Nutbeam, 2008). Generally, limited health literacy should be framed not as a problem of patients and citizens, rather as a challenge to health care providers and health systems to reach out and more effectively communicate with patients, citizens, and families (Kickbusch et al., 2013). Priority areas entail to

- include health literacy as part of school curriculum and life-long learning programs,
- survey and monitor health literacy in the general population as well as in subgroups to target interventions with a participatory approach,
- integrate the health literacy approach in management strategies at all levels in health-associated organizations,
- develop the health literacy of interdisciplinary staff involved in health care, disease prevention, and health promotion,
- identify the cost-effectiveness of health literacy-associated actions, and
- highlight health literacy as an ethical virtue that enhances people-centeredness in health.

The increased focus on cocreation of health between citizens and health providers requires a combination of personal and social responsibility not only from the individuals themselves, but even more so from societal institutions to promote choice, empowerment, self-management, responsiveness, and active and self-directed participation in health and well-being (Kickbusch et al., 2013). The people-centered approach that health literacy is enhancing stimulates self-definition, active realization, and value-driven decision making based on a dual responsibility of the individual and society, which in turn requires freedom of choice and acceptance of diverse outcomes (Sorensen, 2013). The increased global focus on health literacy is expected to qualify health care, disease prevention, and health promotion at large. Yet, to have a profound impact in the future it will require power, priority, and leadership from all involved stakeholders to change the status quo.

Abstract

Measurement of health-related quality of life has become common in health services research and in medical practice. Measures of health-related quality of life can be divided into generic and disease-targeted categories. Generic measures are used to evaluate outcomes from any illness while disease-targeted measures are focused on a particular health condition. Generic measures can be subdivided into psychometric or utility-based. Psychometric methods typically produce a profile of outcomes in which each respondent is given a score on multiple dimensions. Utility-based measures usually summarize health outcomes using a single score that ranges between 0.0 (for death) and 1.0 (for optimum health). Utility-based measures are required for cost/effectiveness analysis. Examples of psychometric measures include the Medical Outcomes Study, the 36-item Short Form, and the Nottingham Health Profile. Decision theory approaches include the EQ-5D, the Health Utilities Index, and the Quality of Well-Being Scale. Examples of disease-targeted measures include the Arthritis Impact Measurement Scale and the University of California, San Diego, Shortness of Breath Questionnaire. Expansion of the number of measures and their applications is expected over the next few years.

Health is probably the most valued human asset. In fact, studies on the preference for different states of being show that virtually everyone rates health as most important. Despite the perceived importance of health, health status has remained difficult to define. There are two common themes in definitions of health. First, premature death is undesirable, so one aspect of health is the avoidance of mortality. The health status of nations is often evaluated in terms of overall mortality rates or infant mortality rates. Second, quality of life is also very important. Disease and disability are of concern because they affect either life expectancy or life quality. For example, cancer and heart disease are the two major causes of premature death in the United States. In addition, disease or disability can make life less desirable. A person with heart disease may face restrictions in daily living activities and may be unable to work or participate in social activities. Even relatively minor diseases and disabilities affect quality of life. A cold, for example, may interfere with the ability to concentrate, work, or attend school. The cold, however, lasts only a short time. A chronic disease, such as arthritis, may affect the quality of life for a long time (Brown et al., 2000).

Within the last few years, medical scientists have come to realize the importance of measuring patient-reported health. Many major diseases, including arthritis, heart disease, and diabetes, or digestive problems are evaluated in terms of the degree to which they affect life quality and life expectancy (Koloski et al., 2000). One can also evaluate treatments for these conditions by the amount of improvement they produce in everyday life. The Food and Drug Administration now considers patient-reported outcomes in their evaluations of new products and nearly all major clinical trials in medicine use quality of life assessment measures. Several approaches to health outcome measurement will be reviewed.

Historical Perspective

For many years, researchers and clinicians have struggled to reach consensus on the measurement of health and health outcomes. Different definitions emphasize related, but divergent, concepts. Some terms used to describe health are positive concepts, such as wellness or normality. Other definitions emphasize negative concepts, such as disability and illness. Much of the debate has centered on whether health is a continuum. Are disability and illness distinct from health, or are they opposite ends of the same continuum? (Patrick and Erickson, 1993).

Because the concept of health lacked conceptual clarity, the World Health Organization (WHO) proposed a comprehensive definition of health in their charter document. Health was defined as "… a state of complete physical, mental, and social well-being and not merely the absence of infirmity" (World Health Organization, 1948). Since the introduction of this definition there has been some convergence of thought. It is now widely recognized that health has multiple dimensions. Further, it is now accepted that measures of mortality alone cannot summarize the health status of populations (Field and Gold, 1998). However, there is still considerable debate about what constitutes health and health status.

Some of the debate about the definition of health originates from sociologists. From the sociological perspective, illness represents deviation from society's standards for physical and mental well-being. Often, this deviation is recognized when individuals cannot perform activities usual for their social roles. In addition to observable functioning, illness may cause reports of symptoms of pain and these deviate from society's norms on wellness. Parsons defined illness as "… a state of disturbance in normal functioning of the total human individual including both the state of the organism as a biological system, and/or his personal and social adjustments" (Parsons, 1951: p. 431). For Parsons, health represented the capacity to perform valued tasks.

The traditional biomedical model is predicated on finding a specific biologic problem and repairing it. In contrast, measures of health outcome consider benefit from the patient's perspective. Successful treatments are those that improve the quality of life or extend life. Most surgical interventions are

justified on the basis of saving lives. However, the great majority of surgical procedures have no effect on life expectancy. For example, four of the most common indications for surgery in the United States are transurethral resection prostatectomy (TURP) for benign hyperplasia of the prostate, extractions of cataracts, joint replacement for severe osteoarthritis of the knee or hip, and hysterectomy for diseases of the uterus. Although it is often argued that these procedures prevent deaths, reviews of the evidence suggest that these procedures are rarely performed to extend life expectancy. In each case, however, the surgery may lead to improvements in functioning or the reporting of symptoms. For example, TURP may reduce the symptom of urinary frequency in men. Cataract extraction may help older patients function better with reading, night driving, and other activities of daily living. Joint arthroplasty may increase mobility for older patients. For most of these cases, traditional physiological measures are limited as outcome assessment. Patients seek these procedures because they want relief of symptoms. Outcomes assessment must consider whether the symptoms are, indeed, relieved. Ultimately, measures of health outcome can be used to evaluate the benefits of treatment from the patient's perspective.

Assessment of Health Outcomes

Methods of assessment of health-related quality of life represent at least two different conceptual traditions. One grows out of the tradition of health status measurement. Several efforts to develop measures of health status were launched in the late 1960s and early 1970s. All the projects were guided by the WHO's definition of health status. The projects resulted in a variety of assessment tools, including the sickness impact profile (SIP) (Bergner et al., 1981), the Quality of Well-Being Scale (QWB) (Kaplan et al., 1995), the 36-item Short Form (SF-36) (Ware and Gandek, 1998), and the Nottingham Health Profile (NHP) (Lowe et al., 1990). Many of the measures examined the effect of disease or disability on the performance of social roles, the ability to interact in the community, and physical functioning. Some of the systems have separate components for the measurement of physical, social, and mental health. The measures also differ in the extent to which they consider subjective aspects of life quality (Brown et al., 2000).

Perhaps the most important distinction between methods to assess quality of life is the contrast between psychometric and decision theory approaches. The psychometric approach attempts to provide separate measures for the many different dimensions of quality of life. Perhaps the best known example of the psychometric tradition is the SIP. The SIP is a 136-item measure that yields 12 different scores displayed in a format similar to an MMPI profile (Bergner et al., 1981).

The decision theory approach attempts to weight the different dimensions of health in order to provide a single expression of health status. Supporters of this approach argue that psychometric methods fail to consider that different health problems are not of equal concern. A runny nose is not the same as severe chest pain. In an experimental trial using the psychometric approach, one will often find that some aspects of quality of life improve while others get worse. For example, a medication might reduce high blood pressure but might also produce headaches and impotence. Many argue that the quality of life notion is the subjective evaluation of observable or objective health states. The decision theory approach attempts to provide an overall measure of quality of life that integrates subjective function states, preferences for these states, morbidity, and mortality.

Common Methods for the Measurement of Quality of Life

A variety of methods have been proposed to measure quality of life, but we cannot review and critique them all here. Instead, we present some of the most widely used psychometric and decision theory-based methods. Readers interested in more detailed reviews should consult Walker and Rosser (1993) and McDowell and Newell (1996).

Psychometric Methods

SF-36

Perhaps the most commonly used outcome measure in the world today is the Medical Outcomes Study (MOS) SF-36. The SF-36 grew out of work by the RAND Corporation and the Medical Outcomes Study (MOS) (Ware and Gandek, 1998). Originally, it was based on the measurement strategy from the RAND Health Insurance Study. The MOS attempted to develop a very short, 20-item instrument known as the Short Form-20 or SF-20. However, the SF-20 did not have appropriate reliability for some dimensions. The SF-36 includes eight health concepts: physical functioning, role-physical, bodily pain, general health perceptions, vitality, social functioning, role-emotional, and mental health (Kosinski et al., 1999). The SF-36 can be either administered by a trained interviewer or self-administered. It has many advantages. For example, it is brief, and there is substantial evidence for its reliability and validity. The SF-36 can be machine scored and has been evaluated in large population studies. The reliability and validity of the SF-36 are well documented (Keller et al., 1999; Scott-Lennox et al., 1999; Stewart and Ware, 1992; Ware and Gandek, 1998).

Despite its many advantages, the SF-36 also presents some disadvantages. For example, it does not have age-specific questions and one cannot clearly determine whether it is equally appropriate at each level of the age continuum. The items for older retired individuals are the same as those for children (Stewart and Ware, 1992). Nevertheless, the SF-36 has become the most commonly used behavioral measure in contemporary medicine.

Nottingham Health Profile

The NHP is another profile approach that has been used widely in Europe. One of the important features of the NHP is that the items were originally generated on the basis of extensive discussions with patients. The NHP has two parts. The first includes 38 items divided into six categories: sleep, physical mobility, energy, pain, emotional reactions, and social isolation. Items within each of these sections are rated in terms of relative importance. Items are rescaled in order to allow them to vary between 0 and 100 within each section. The second part

of the NHP includes seven statements related to the areas of life most affected by health: employment, household activities, social life, home life, sex life, hobbies and interests, and holidays. The respondent indicates whether or not a health condition has affected his or her life in these areas. Used in a substantial number of studies, the NHP has considerable evidence for its reliability and validity.

An important strength of the NHP is that it is based on consumer definitions of health derived from individuals in the community. The language in the NHP is simple and the scale requires only a low level of reading ability. Psychometric properties of the NHP have been evaluated in a substantial number of studies. However, the NHP, like most profile measures, does not provide relative-importance weightings across dimensions. As a result, it is difficult to compare the dimensions directly with one another (Lowe et al., 1990).

Decision Theory Approaches

Within the last few years, interest has grown in using quality of life data to help evaluate the cost/utility or cost-effectiveness of health care programs. Cost studies have gained in popularity because health care costs have grown so rapidly in recent years. Not all health care interventions equally return benefit for the expended dollar. Objective cost studies might guide policy makers toward an optimal and equitable distribution of scarce resources. Cost-effectiveness analysis typically quantifies the benefits of a health care intervention in terms of years of life, or quality-adjusted life years (QALYs). Cost/utility is a special case of cost-effectiveness that weights observable health states by preferences or utility judgments of quality. In cost/utility analysis, the benefits of medical care, behavioral interventions, or preventive programs are expressed in terms of years of life adjusted for reduced quality of life or QALYs.

If a man dies of heart disease at 50 years of age and we expected him to live to 75 years of age, we might conclude that the disease precipitated 25 lost life-years. If 100 men died at 50 years of age (and also had a life expectancy of 75 years), we might conclude that 2500 (100 men $\times$ 25 years) life-years had been lost. Yet death is not the only relevant outcome of heart disease. Many adults suffer myocardial infarctions that leave them somewhat disabled for a long time. Though still alive, they suffer diminished quality of life. QALYs take into consideration such consequences. For example, a disease that reduces quality of life by one-half will take away 0.5 QALY over the course of each year. If the disease affects two people, it will take away 1 year (2×0.5) over each year. A medical treatment that improves quality of life by 0.2 for each of five individuals will result in the equivalent of 1 QALY if the benefit persists for 1 year. This system has the advantage of considering both benefits and side effects of programs in terms of the common QALY units.

The need to integrate mortality and quality of life information is clearly apparent in studies of heart disease. Consider hypertension. People with high blood pressure may live shorter lives if untreated, longer if treated. Thus, one benefit of treatment is to add years to life. However, for most patients, high blood pressure does not produce symptoms for many years. Conversely, the treatment for high blood pressure may cause negative side effects. If one evaluates a treatment only in terms of changes in life expectancy, the benefits of the program will be overestimated because one has not taken side effects into consideration. On the other hand, considering only current quality of life will underestimate the treatment benefits, because information on mortality (death) is excluded. In fact, considering only current function might make the treatment look harmful because the side effects of the treatment might be worse than the symptoms of hypertension. A comprehensive measurement system takes into consideration side effects and benefits and provides an overall estimate of the benefit of treatment (Russell, 1986).

Of the several different approaches for obtaining QALYs, most are similar. The three most commonly used methods are the EQ-5D, the Health Utilities Index (HUI), and the QWB.

EQ-5D

The approach most commonly used in the European community in the late twentieth century was the EQ-5D. This method was developed by a collaborative group from Western Europe, led by Paul Kind and associates, known as the EuroQol group (Kind, 1997). The intention of this effort was to develop a generic currency for health that could be used commonly across Europe. The concept of a common EuroQol was stimulated by the desire for a common European currency – the Euro dollar. The original version of the EuroQol had 14 health states in six different domains. In addition, respondents placed their health on a continuum ranging from death (0.0) to perfect health (1.0). The method was validated in postal surveys in England, Sweden, and the Netherlands. More recent versions of the EuroQol, known as the EQ-5D, are now in use in a substantial number of clinical and population studies (Gudex et al., 1996; Hurst et al., 1997). Although the EQ-5D is easy to use and comprehensive, there have been some problems with ceiling effects. Substantial numbers of people obtain the highest possible score.

Health Utilities Index

Another approach has been developed in Canada by Torrance et al. (1996). This method, known as the HUI, is derived from microeconomic theory. There have been several versions of the measure, typically identified by 'Mark.' The HUI Mark I was developed for studies in the neonatal intensive care unit. The measure had 960 unique health states. In 1992, the HUI Mark II was developed and included 24 000 unique health states. The HUI Mark III, released in 1995, had 972 000 health states. Eight components of the HUI Mark III include vision (six levels), hearing (six levels), speech (five levels), ambulation (six levels), dexterity (six levels), emotion (five levels), cognition (six levels), and pain (five levels). Multiplying the number of levels across the eight dimensions gives the 972 000 states.

Using multiattribute utility scaling methods, judges evaluate levels of wellness associated with each level of each domain. A multiattribute model is used to map preference for the 972 000 possible states onto the 0.0 to 1.0 continuum. The HUI has been used in many population and clinical studies. For overall health status, men obtain higher scores early in the life cycle. However, after about the 45 years of age, women obtain higher scores and this difference grows systematically through the remainder of the life span (Kaplan and Erickson, 2000).

Quality of Well-Being Scale

A third method, known as the QWB, integrates several components into a single score. First, patients are classified according to objective levels of functioning. These levels are represented by the scales of mobility, physical activity, and social activity. Once observable behavioral levels of functioning have been classified, each individual is placed on the 0.0 to 1.0 scale of wellness, which describes where a person lies on the continuum between optimum function and death.

To accomplish this, the observable health states are weighted by quality ratings for the desirability of these conditions. Human value studies have been conducted to place the observable states onto a preference continuum, with an anchor of 0.0 for death and 1.0 for completely well. Studies have shown that the weights are highly stable over a 1-year period and that they are consistent across diverse groups of raters. Finally, one must consider the duration of stay in various health states. Having a cough or a headache for 1 day is not the same as having the problem for 1 year. A health measure must take these durations into consideration. Using this information, one can describe health-related quality of life in terms similar to years of life. For example, 1 year in a state assigned the weight of 0.5 is equivalent to 0.5 of a QALY.

Cost-Effectiveness Evaluations

Utility-based measures of quality of life are often used to evaluate the cost-effectiveness of health care programs (Kaplan et al., 1997). For example, one study using the QWB showed a new medication for patients with arthritis produced an average of 0.023 QALY per year, whereas a new medication for AIDS produced nearly 0.46 of these units per year. However, the benefit of the arthritis medication may last as long as 20 years, ultimately producing 0.023×20 years $= 0.46$ year. The AIDS treatment produced a benefit for only 1 year, so its total effect was 0.46×1 year $= 0.46$ year. In other words, the general system allows the full potential benefits of these two very different treatments to be compared (Kaplan et al., 1995).

QALYs are generic measures of life expectancy with adjustments for quality of life (Gold, 1996). QALYs consider both benefits and side effects of programs in terms of the common outcome units. Although QALYs are typically assessed for patients, they can also be measured for others, including care givers who are placed at risk because they experience stressful life events. The Institute of Medicine recommended that population health metrics be used to evaluate public programs and to assist the decision-making process (Field and Gold, 1998).

In addition to health benefits, programs also have costs. Resources are limited and good policy requires the allocation of resources to maximize life expectancy and health-related quality of life. Thus, in addition to measuring health outcomes, costs must also be considered. Methodologies for estimating costs have now become standardized (Gold, 1996). From an administrative perspective, cost estimates include all costs of treatment and costs associated with caring for any side effects of treatment. From a social perspective, costs are broader and may include the costs of family members staying off work to provide care. Comparing programs for a given population with a given medical condition, cost-effectiveness is measured as the change in costs of care for the program compared with the existing therapy or program, relative to the change in health measured in a standardized unit such as the QALY. The difference in costs over the difference in effectiveness is the *incremental cost-effectiveness* and is usually expressed as the cost/QALY. Since the objective of all programs is to produce QALYs, the cost/QALY ratio can be used to show the relative efficiency of different programs (Gold, 1996).

Some traditional interventions, such as bypass surgery for one-vessel coronary heart disease, may cost as much as $700 000 to produce a QALY. Screening programs, such as mammography, may also require many resources to produce a QALY. On the other hand, public health programs such as pneumonia vaccines for the elderly or laws requiring children to be in infant seats and adults to be in seat belts in motorcars may produce a QALY at a very low cost. It might be argued that programs to the left of the pay line should be funded, but those with cost/QALY ratios to the right of the line should be examined more carefully.

Disease-Specific Measures

This article has focused on generic measures of health outcome. These measures can usually be applied to any age, gender, or ethnic group. In most cases age- and gender-related norms are available. However, there are a significantly larger number of situation-specific measures. Some of these measures are appropriate for a particular age, gender, or ethnic group. For example, several measures are designed specifically to assess health outcomes in children. Most often, the measures are disease-specific, meaning that they are designed to assess outcomes of a particular health problem. Validated measures of health outcome are available for illnesses such as arthritis, diabetes, heart disease, kidney failure, and virtually every other major health condition. Two examples are the Arthritis Impact Measurement Scale (AIMS) (Meenan, 1982) and the UCSD Shortness of Breath Questionnaire (SOBQ) used in studies of patients with emphysema (Eakin et al., 1998).

The AIMS is a health index designed at the Multipurpose Arthritis Center at Boston University. It is intended to measure physical health and social well-being for patients with rheumatoid arthritis (Meenan, 1982). The resultant scale includes 67 items, with questions about functioning, health perceptions, morbidity, and demographics. The AIMS contains scales for mobility, physical activity, social activity, activities of daily living, depression and anxiety, and arthritis-related symptoms. In effect, it is an adaptation of an early version of the QWB (Eakin et al., 1998), with a series of items designed to tap more specifically the effect of arthritis upon functioning and the quality of life. Factor analysis of the AIMS has produced three subscales: physical function, psychological function, and pain. Most current applications of the AIMS use composite scores for these three areas.

The University of California, San Diego, SOBQ includes 25 items that evaluate self-reported shortness of breath during the performance of various activities of daily living. Evaluations of the measure show it highly correlated with other quality of life measures such as the QWB and the Center for Epidemiologic Studies Depression Scale. The measure has high internal consistency (alpha $= 0.96$) and is significantly correlated with

performance measures such as the distance that can be walked in 6 min (Eakin et al., 1998).

Summary

The assessment of patient-reported experience has become a standard component of health outcome evaluation. There are several important distinctions between commonly used approaches. Generic measures are used to evaluate the health outcome for any illness or disease of state. Generic measures can typically be classified as derived from psychometric or decision theory. Psychometric approaches include the SIP, the SF-36, and the NHP. Decision theory approaches are used to estimate outcomes in terms of QALYs. Methods used for this purpose include the EQ-5D, the HUI, and the QWB. Disease-specific measures are available for a wide variety of health conditions. Although disease-specific measures may be more sensitive for outcomes of a particular condition, they cannot be used for cross-illness comparisons or for cost-effectiveness analysis. The assessment of health outcome is a rapidly developing field and we anticipate major new developments over the next decade.

Editors Note

Since the original publication of Dr. Kaplan's article, the literature on assessment of health outcomes has continued to evolve. One significant development has been the development of the Patient-Reported Outcomes Measurement Information System (PROMIS), a standardized data reporting and database system specifically to keep track of patient-reported health outcomes (see David Cella et al., 2010). A useful assessment of this and related assessment tools in health settings can be found in Jill Dawson et al. (2010) (see also Claire F. Snyder et al., 2012).

The search for causes, correlates, and predictors of untoward health outcomes continues apace. Two factors that have figured prominently in recent literature are health literacy and sedentary life styles. Health literacy is an issue because if patients do not understand their doctors or medical regimens, they are far less compliant than otherwise. A useful review of the many studies reaching this conclusion is Nancy D. Berkman et al. (2011). Likewise, those whose sedentary lives bespeak their general indifference to their own well-being also do not report or achieve promising health outcomes; for a review of this voluminous literature, see Karin I. Proper et al. (2011).

The general concern with patient-reported outcomes signals a shift in contemporary medical care toward so-called 'patient-centered' or 'goal-oriented' patient care. Useful descriptions of this larger health care 'movement' are Ronald M. Epstein and Richard L. Street (2011) and David B. Reuben and Mary E. Tinetti (2012).

Health Politics and Policy

Abstract

Healthcare politics and policy cover two main areas. Healthcare politics refers to how healthcare systems are regulated and governed and maintains a focus on the influence of actors and political institutions. Healthcare policy covers healthcare system characteristics and thus how these systems function. This article, first, provides information about actors and political institutions as well as modes of governance in the field of healthcare. Second, it introduces main characteristics of healthcare systems with respect to healthcare expenditure, financing, service provision, and institutional regulations.

Introduction

Health is considered the most important 'good' of modern society. Due to its great value, attempts have long been made to provide security in the case of sickness. Throughout the nineteenth century, voluntary sickness funds, friendly societies, trade unions, and other organizations began providing coverage in the case of sickness, mainly offering a sickness benefit to protect income when the family's main breadwinner could no longer work because of illness. Partly related to the fact that voluntary organizations could not cover the parts of the population most in need, the state began to step in by the end of the nineteenth century. First, Social Health Insurance (SHI) systems were established (in 1883 in Germany, followed by Austria in 1888, Denmark in 1892, and Great Britain in 1911). One main reason for implementing social insurance in Germany was that the national government had no resources (taxes) to cover the costs and therefore decided to finance public healthcare on the basis of social insurance contributions. Only later did the state assume an even greater role and, in addition to providing the regulatory framework, financed healthcare through taxation starting with the British National Health Service (NHS) in 1946/48 (Klein, 2010).

The term health policy generally describes public policy in the healthcare arena; the role of health policy actors and different modes of governance; the three main dimensions of 'financing,' 'service provision,' and 'regulation'; as well as how healthcare systems are organized. The healthcare arena is characterized by high costs (with some countries spending more than 10% of their GDP on healthcare) and high provider density (with some public healthcare systems being the largest employer in their respective country). Countries have found various forms to organize healthcare. Many of them still resemble either an SHI type of system and an NHS type. A closer look, however, identifies important differences within the respective type. SHI systems from Central and Eastern Europe, for instance, differ from Western SHI systems due to weak corporate actors and a stronger role of the state. Compared with the British NHS, Scandinavian NHS systems are characterized by a stronger influence of regional and local state actors, and Southern European NHS systems suffer from weak administrative capacities.

Data

This article covers OECD countries (Organization for Economic Cooperation and Development). In addition to national sources, the OECD Health Data and the World Health Organization's Health for All Database represent the best modern data sources for international comparison. Increasingly up-to-date country information is given by the European Observatory on Health Systems and Policies covering healthcare systems and reforms both in Europe as well as in some non-European countries (for databases, see web sites below; for international comparison, *see* Welfare Policy Comparisons in this volume).

Actors

The healthcare arena is characterized by more actors (including organized interests) than most other areas of the welfare state. One reason for the involvement of multiple actors is that healthcare is 'service heavy' in contrast to other social policy fields that concentrate on financial transfers (e.g., pensions and unemployment benefits; e.g., *see* Pension Policy in this volume). Actors are not only involved in the financing but also in the delivery of care, and this higher level of complexity (e.g., negotiations among financing agencies and providers) has led to the involvement of multiple actors.

The healthcare arena can be divided into three sections: financing, healthcare provision, and regulation. Three different groups of actors can be involved in each of the three sections: the state, private not-for-profit actors, and private for-profit actors (Rothgang et al., 2010). State actors are present at the national, regional, and local levels. In the British NHS, decision-making in healthcare is still top–down, and the greatest influence is exerted by the Department of Health. However, even in the hierarchical British system, other forms of governance have become increasingly influential, such as the implementation of a purchaser–provider split and other market elements. In other countries, the regional level is of great relevance, as is the case in Denmark, whose regions are responsible for the hospital sector, and Germany, where the Bundesländer cover hospitals' investment costs. In primary healthcare and prevention, local-level actors such as the Danish

municipalities are often responsible. Characterizing private not-for-profit actors is somewhat more difficult. They can be defined as nonstate actors that have no for-profit motives. SHI funds fall into this category and have, by state regulation, received quasi-governmental responsibilities but maintain autonomy from direct state intervention. Welfare organizations that traditionally run hospitals in a number of countries offer another example. Although they may be major players in a country's hospital market, they are not allowed to make profits. Private for-profit actors represent a third group. Private hospitals, private health insurance funds, self-employed doctors, and other self-employed healthcare providers fall under this category.

Governance

In her comparison of France, Sweden, and Switzerland, Immergut (1992) focused on the veto potential of interest groups in different settings and showed that veto opportunities arise out of the specific features of political institutions. Her study suggests that until the late 1980s, the impact of physicians' organizations on health policy may have been much less decisive than was generally believed. Immergut concluded that veto points in the political system are of greater importance than veto groups within society.

Tuohy (1999) provided the most theoretical approach to models of governance. She proposed that the dominant model of accountability in healthcare changed from agency to contract models. In the older, trust-based, principal–agent relationship, the state (the principal) delegated authority for the regulation and distribution of healthcare to the medical profession (the agent). As a result of better access to information, the medical profession dominated this model of governance until the end of the twentieth century. New information technologies have since provided governments with better information, reducing the information asymmetry between the state and the medical profession. In a contract model, the state's role is to purchase rather than to simply finance healthcare. The medical profession's loss of autonomy is due less to cost pressures than to the way in which the provision and verification of detailed medical information strengthen governments' power.

In his concept of 'the health care state,' Moran (1999) classified healthcare systems according to three governing concepts: consumption, provision, and production. By consumption, Moran refers to patients' basis of eligibility for access to healthcare and to financing mechanisms. The provision dimension encompasses the control of hospitals and doctors, and the production dimension encompasses mechanisms that regulate medical innovation. Based on these dimensions, Moran constructed four types of healthcare states: the 'entrenched command-and-control state' (Scandinavian countries, Great Britain), the 'supply state' (United States), the 'corporatist state' (Germany), and the 'insecure command-and-control state' (Greece, Portugal). 'Supply states' are dominated by provider interests in all three dimensions, and it is this domination of suppliers, not the operation of market principles, that Moran considers the primary problem with American healthcare. In 'command-and-control states,' on the other hand, the state is distinctive in all three governing areas. Despite providing universal healthcare in legal terms, Southern Europe's 'insecure command-and-control states' lack the administrative capacity for guaranteeing universal coverage and equal access to care – principles that have characterized the Nordic countries and Great Britain for many decades. In 'corporatist healthcare states,' finally, public law bodies and doctors' associations are dominant.

Financing

Healthcare can be financed by state taxes, social insurance contributions, private insurance contributions, and private copayments. The first two modes of financing represent the idea that access to medical care should not depend on the size of the patients' bank account. In private health insurance, in contrast, insurance contributions are not income related, and redistribution among social groups is low. Private copayments force patients to participate directly in the costs of their sickness and thus represent a particular burden for those in poor health and for lower income groups. Despite much debate about privatization in healthcare, there is currently only a slight retreat of the state at the aggregate level. However, private healthcare financing has become dominant in certain sectors. In most OECD countries, the private share for the financing of pharmaceuticals is above 40% and far above 50% for the financing of dentures (OECD Health Data, 2012).

Among OECD countries, the share of public healthcare financing (taxes and social insurance contributions) displays a modest decrease from more than 76% in the early 1980s to 73% in the 1990s (Rothgang et al., 2010). Countries such as Britain (81.9%), Sweden (81.6%), and Denmark (79.3%) have remained primarily tax financed. France, Germany, and Belgium have continued to rely to a vast extent on social insurance contributions, with shares of 74.3, 67.3, and 61.6%, respectively. A few countries, including the United States (55.6%) and South Korea (47.9%), are financed predominantly by private sources (private insurance and private out-of-pocket). In these countries, however, the private share has decreased since the early 1990s. Moreover, there are some mixed financing systems. In Switzerland and Israel, the shares of both private and social insurance financing are about the same, and Turkey has similar shares of tax, social insurance, and private financing (see **Table 1**).

Provision

In healthcare provision, the role of the state has always been less pronounced than in healthcare financing. In the outpatient sector, healthcare services have mainly been offered by private for-profit actors. Although healthcare providers' access to the healthcare market is strictly regulated (through access to medical schools and through service providers' access to the healthcare market), providers can be defined as private for-profit actors due to their for-profit orientation. In inpatient healthcare, in contrast, we can distinguish between public, private not-for-profit, and private for-profit hospitals. The role of the state (or the public–private mix) in healthcare provision therefore depends on the share of the outpatient sector as well as on the

share of public, private not-for-profit, and private for-profit hospitals. The size of the outpatient healthcare sector depends on whether specialists have the right to open up their own practice or not. In countries such as Denmark and Great Britain, most specialists work in hospitals, and only a few specialists are allowed to become self-employed and open up their own practice or outpatient clinic. The outpatient sector is therefore much smaller compared with that of the United States and Germany, where both general practitioners and specialists are allowed to provide ambulatory healthcare outside hospitals.

Some countries' hospital sector is almost exclusively public (Denmark, Finland, Great Britain, Sweden), while a few rely primarily on private for-profit providers (e.g., South Korea). In the United States, most hospitals are private but maintain nonprofit status. Here, as in Germany, Austria, and France, inpatient care beds are provided through public, private nonprofit, and private for-profit organizations. In Western Europe, there is a long tradition of private nonprofit hospitals. Only in a few countries is the private for-profit hospital sector growing to a great extent, most prominently in Germany, where the share of private for-profit hospital beds as a percentage of total beds has more than tripled, from 4% in 1991 to 15% in 2007 (Rothgang et al., 2010).

Taking all healthcare sectors together, OECD countries display a huge variety in the state's role in service provision, ranging from a public share below 10% in countries such as the United States and the Netherlands to a share of more than 60% in countries such as Finland, Iceland, and Great Britain. As a rule, private (non- and for-profit) provision prevails in market-based and SHI systems, while NHS systems rely more often on public service delivery. However, the public share of healthcare service provision in almost all countries is currently declining, while private (particularly for-profit) service provision is growing.

International comparison thus shows a slight retreat of the state in healthcare financing and a somewhat more pronounced retreat of the state in direct service provision. Both dimensions – financing and service provision – still show vast country variations with respect to the public–private mix.

Regulation

Healthcare can be directly regulated by state actors, by corporate actors in a system of self-regulation, or by market mechanisms. Regulation focuses on the relationship between three sets of actors, that is, healthcare providers, financing bodies, and beneficiaries of the healthcare system. As shown in Table 2, regulation concerns six areas.

Some healthcare systems, most prominently the British NHS, have a long tradition of hierarchical state intervention. Most healthcare policy issues have been regulated at the national level. The growth of market mechanisms in the British NHS that began with the introduction of the internal market in the early 1990s is well known (Klein, 2010). The purchaser–provider split doubtlessly triggered profound organizational changes. However, at the same time, evidence from the initial years of the internal market reveals that little measurable change occurred. About 10 years later, the Healthcare Commission became responsible for both the public and

private sectors and began setting standards as well as engaging in the inspection and assessment of performance, clinical governance, and finance in addition to promoting improvements in healthcare provision. Thus, the market and state regulation in Britain has become more powerful over the past decades (Rothgang et al., 2010).

The state is not only active at the national level. Other examples of strong state intervention include Denmark and Sweden, which demonstrate a major role of the state in both financing and service provision. In contrast to Britain, regulation does not take place at the national but primarily at the regional and local levels. In Denmark, for instance, regions are responsible for the hospital sector while municipalities are in charge of primary healthcare provided by general practitioners, school nurses, and salaried dentists for children in public dental clinics. As in Britain, Sweden has experimented with introducing a purchaser–provider split, and Denmark and Sweden have sought to strengthen competition by giving more room to private hospitals. Freeman and Moran (2000) have argued that 'competition,' which was on the political agenda of a number of healthcare systems in the 1990s, quickly turned into collaboration among larger units of healthcare provision: "In health care we encounter the wider paradox of public policies that try to strengthen market forces: markets need states, and strong markets need strong states" (Freeman and Moran, 2000: 56). Again, Britain is a good example, with Primary Care Trusts, that is, larger collaborative healthcare units, which control about 75% of the NHS budget (Klein, 2010).

Alongside state regulation, a number of countries are characterized by self-regulation, in which corporate actors are responsible for areas of the healthcare system such as financing, remuneration, and the definition of the benefit package (see areas of regulation in **Table 2**). In Germany, sickness funds are self-administered by a professional board and a supervisory board, which generally consist of employees and employers' representatives. Sickness funds, much like panel doctor associations as their negotiating partners in the provision of ambulatory medical care, are public corporations. Since the early 1990s, the self-regulatory core of the German system has come under pressure. Free choice of sickness funds for patients (and thus competition among funds) was introduced in 1993. Competition and other market instruments have since been complemented by a 'risk structure equalization scheme' with financial redistribution to compensate for the different risk structures of funds related to age, gender, number of dependent family members, disability, income, and (since 2007) also differences in the morbidity structure. Furthermore, since 2009, the contribution rates to sickness funds have been set by the national government instead of by the individual sickness funds, as was previously the case. Thus, more competition and more direct state intervention have entered the German SHI at the expense of self-regulation. Within the system of self-regulation, sickness funds have become stronger while doctors' associations have lost part of their former power. In Austria, sickness funds and doctors' associations are also autonomous actors. However, state intervention has always been stronger than in Germany. For instance, contribution rates were for many years fixed by the state as opposed to the sickness funds, resulting in much lower contribution rates in Austria compared with Germany.

The US healthcare system gives greater scope to markets than do other OECD healthcare systems. However, far from being a pure 'private market model,' it combines social insurance elements (Medicare), means-tested programs (Medicaid), private insurance, and direct private out-of-pocket payments. Private health insurance (often in the form of company-based plans), which is the first line of protection against the risk of medical costs for most Americans, is heavily regulated by the state and today provides collective coverage for about 70% of the US population. Since the 1960s, public programs such as Medicare and Medicaid have become increasingly important and today cover about 25% of the population. Since private insurance is also heavily tax subsidized, about half of total healthcare expenditure is financed via public funds (Rothgang et al., 2010). Private out-of-pocket financing was reduced from 48.5% of the total healthcare expenditure in 1960 to 13.2% in 2005 (OECD Health Data, 2012). At the same time, more than 17% of the US population below the age of 65 is without coverage by private or public schemes in the case of sickness (White, 2007). Thus, policies with strong emphasis on private solutions leave room for the exclusion of larger groups of society from access to healthcare, even if healthcare services are financed to a large degree out of the public purse.

Healthcare Systems

Comparative healthcare policy captures the financing, provision, and regulation of medical care. There are several studies that individually consider financing, provision, and regulation (for an overview, see Marmor and Wendt, 2012); however, few comparisons capture all three dimensions (with the notable exception of the textbooks by Blank and Burau (2010) and Gauld (2009)). Such comparison is important for improving our knowledge of how healthcare systems function and what they produce. In particular, combining information from healthcare systems and outcomes such as health status, health inequalities, access to healthcare, and patients' perceptions of medical care arrangements help to better inform health policy decision-making. Healthcare systems can be captured using the dimensions of expenditure, financing, healthcare provision, and regulation.

Expenditure is generally measured either in monetary units per head of population (often in US$ or Euros by using purchasing power parities, or ppp) or as a percentage of countries' gross domestic product (GDP). Healthcare expenditure as a percentage of GDP indicates the amount a society is able or willing to spend on healthcare. Healthcare expenditure in monetary units per head indicates the actual amount a society invests in its members' health on average. Wealthier societies often invest a higher share than do less affluent ones. However, in recent decades, cost containment in healthcare has become a global issue, and the level of resources spent on healthcare has become related less to the level of GDP and more to institutional characteristics of the respective healthcare system. Today, there is a strong negative correlation between the share of public financing and the share of GDP invested in healthcare (Wendt and Kohl, 2010). Countries with a higher share of public financing have been more successful at controlling costs, whereas the United States, which gives

a higher scope to the market and to private health insurance than do most other OECD healthcare systems, spends the highest amount of money on healthcare worldwide.

The second dimension for comparing healthcare systems, namely financing, has already been discussed above. The public share of healthcare financing (particularly tax financing) indicates the interventional power of the state in healthcare. For patients, the mode of financing (taxes, social health insurance, private health insurance, and private copayments) signals coverage, solidarity, and according to Jacob Hacker, the privatization of social risks in the case of sickness (see Marmor and Wendt, 2011). In tax-financed NHS systems, coverage is generally provided on the basis of citizenship; in SHI systems, the provision is on the basis of contribution payments, which often cover dependent family members without own contribution payments. As a rule, both types of financing allow for a high level of redistribution and thus solidarity among their respective populations. Taxes and social insurance contributions are generally related to income, and we find a high redistribution from higher to lower income groups. However, countries such as the Netherlands have introduced flat-rate premiums with the effect of lowering redistribution among certain income groups. Furthermore, in tax- and social insurance-financed systems, we find redistribution from younger to older age groups due to a higher take-up rate of healthcare by older people, from single households to family households with children (if the children are covered without own contributions), and from those in good health to those in poor health since taxes and social insurance premiums are not related to health status. In private health insurance, in contrast, premiums are set irrespective of income and are therefore a greater burden for lower income groups, children are covered by own insurance premiums and there is thus no redistribution toward families with children, and contributions are calculated on the basis of age and health and as a consequence, redistribution among health- and age groups is lower than in tax- and social insurance-financed systems. In the case of direct private out-of-pocket payments, patients participate directly in the costs of healthcare. The higher the share of private out-of-pocket financing, the greater the privatization of risk in the case of sickness and therefore, especially for lower-income groups, the greater the barriers to accessing healthcare services.

The third dimension, healthcare provision, is more difficult to measure than expenditure and financing. Total healthcare employment includes different categories of providers and qualification levels. The main categories of healthcare providers are medical doctors (general practitioners and specialists), nurses, dentists, pharmacists, midwifes, physiotherapists, and doctor's assistants. On average, the number of practicing physicians in OECD countries has increased from about 2.6 per 1000 inhabitants in 1995 to 3.0 per 1000 inhabitants in 2008. We find the highest density of physicians in Austria (4.7 in 2009) and the lowest density in Korea (1.9 in 2009). Other provider groups have experienced similar developments and variations. Today, we find the highest numbers of practicing nurses in Denmark, Finland, Iceland, Norway, and Switzerland, with levels above 14 per 1000 inhabitants, and the lowest numbers in Greece, Korea, and Mexico, with levels below 5 per 1000 inhabitants. While the number of healthcare personnel has increased on average, most OECD countries have opted for a reduction of hospital beds and the average length of stay. The average length of acute hospital stays was reduced from around 8.5 days in 1995 to around 6.5 days in 2008 (OECD mean), with a current range of 19 days in Japan to less than 4 days in Denmark. The average number of acute care beds per 1000 population was reduced from 4.6 in 1995 to 3.6 in 2008 (OECD mean), with a range of 8.1 beds in Japan to 1.6 beds in Mexico (OECD Health Data, 2012). The reductions of hospital beds and the length of hospital stays are partly related to the financing of hospitals on the basis of diagnosis-related groups, which set incentives for shorter hospital stays. However, the Scandinavian countries demonstrate that shorter hospital stays require intensive collaboration between hospitals and social-care units at the local level. Without well-established social care, the quality of service provision may decrease when patients are cared for outside the hospital and, as the US example has demonstrated, overall costs may even increase (Reinhardt, 2011).

In regulation, finally, comparative studies focus on issues such as patients' access to healthcare and doctors' remuneration. While scholars of politics typically ask *who* is responsible for governance and regulation, policy studies tend to focus on *how* healthcare is organized and what the consequences of its structure are (Marmor and Wendt, 2012). Access regulation captures whether patients have free choice of medical doctors or whether they have to sign up on a GP's list for a longer period of time. Here, we find a broad spectrum of systems, including strict access regulation in countries such as Denmark, the Netherlands, and Great Britain, where patients have to sign up on a GP's list and need a referral to access specialist healthcare. Today, only a few countries (e.g., Switzerland) do not require registration with a GP and allow free choice and direct access to specialists. Most OECD countries have introduced some kind of access regulation and require either a referral from a GP or additional copayments when visiting a specialist without a referral. Belgium and France, social insurance countries with traditionally unregulated access to specialists, have introduced gatekeeping elements through financial incentives. In the United States, private insurance conventional indemnity coverage is still an example of free choice, while US managed care (e.g., Health Maintenance Organizations/HMOs, Preferred Provider Organizations/PPOs) restrict patients' choice of both GPs and specialists (Reibling and Wendt, 2012).

The issue of remuneration is important since the remuneration method indicates the degree of doctors' autonomy from state control (Moran, 1999) and presumably also influences the level of healthcare provided. There are four kinds of remuneration of medical doctors, and they can be paid on the basis of fee-for-service, per case, per capita (the number of patients on a doctor's list), or by a salary. Control over doctors' income is highest when paying a salary and lowest under a fee-for-service scheme. The reimbursement method also affects the way doctors alter their workload, and as a rule, fee-for-service methods result in both more active treatment by and higher income for doctors. A fee-for-service payment may set an incentive for the doctor to see his or her patients as often as possible, while reimbursement per capita or a fixed salary may set an incentive for reducing the workload. Countries often combine different remuneration methods, for example,

per-capita payment with either a salary or flat-rate payment (Denmark, Great Britain) or fee-for-service with per-case reimbursement (Germany). When focusing on the main method of GP remuneration, about the same number of countries within the OECD show a preference for fee-for-service (e.g., Austria, Belgium, France, Germany, Japan, Switzerland, United States) and for capitation payment (e.g., Australia, Denmark, the Netherlands, Poland, Great Britain), while fewer countries show a preference for fixed-salary components (e.g., Finland, Israel, Spain, Sweden) (see the European Observatory of Health Systems and Policies).

The healthcare system characteristics presented here have been used for cross-country comparison (see Marmor and Wendt, 2012, for an overview). A meaningful selection of dimensions and characteristics, however, depends on the research question. Access to healthcare providers and the remuneration of medical doctors can be used for analyzing the effects of institutional characteristics on inequalities of healthcare utilization. Additional questions require other healthcare system indicators, for example, for measuring effects on health status and health inequalities and for analyzing healthcare system transformation and related social dynamics (Kuhlmann and Annendale, 2012).

Conclusion

Retrenchment in healthcare is only in its beginning stages, and access to affordable healthcare for the entire population will remain on the political agenda for some time to come. In particular, healthcare costs are expected to increase as a result of demographic changes. Since healthcare is 'service heavy,' efficiency gains are more difficult to achieve than in other areas of the welfare state. Healthcare systems with a high share of public financing have proven more successful in controlling healthcare costs than have private ones. Market-based US healthcare remains the most expensive healthcare system worldwide without also being able to achieve a leading position in healthcare provision. Increasing direct private payments in OECD countries would not only increase the privatization of social risks in the field of healthcare, but would also abolish the necessity of effective cost–control mechanisms. The governance of patients' access to healthcare providers, rather than financial burdens, may lead to a reduced but more equal distribution of necessary healthcare services. Over the past decades, the degree of regulation concerning patients' access to healthcare providers has increased, and this process can be expected to continue. At the same time, the issue of patients' choice is becoming more prominent, particularly in countries with a traditionally high level of access regulation. Patients' choice among larger units of healthcare delivery may eventually combine the goals of cost control, guidance for patients' through the healthcare system, and patients' choice.

Health Promotion in Schools

Abstract

In the past two decades, an increasing number of school-based mental health programs and services have been developed and implemented. In this overview, quantitative reviews of prevention and intervention programs targeting adolescent obesity, drug use, smoking, alcohol consumption, and aggressive and violent behaviors such as bullying are presented. Research into the effectiveness of comprehensive school health programs provides evidence of the positive influence of these programs on student health behaviors. However, conditions that initiate and maintain effective school health promotion programs depend on several school-based organizational and program implementation factors. Therefore, implications for school health programs and personnel are given.

Several World Health Organization (WHO) reports have reported an increase in obesity, diabetes, and cardiovascular and other diseases among children and adolescents and outlined the high prevalence of unhealthy diets, alcohol and tobacco use, and inactive lifestyles as causal factors among the youth (Jepson et al., 2010). Therefore, preventing unhealthy lifestyles and promoting health-enhancing behaviors as early as possible are important objectives. For this reason, health promotion in schools is a topic of both practical and empirical interest.

Schools that provide comprehensive school health promotion programs are more effective in encouraging children to adopt health-enhancing behaviors and reducing health-compromising behaviors than schools that provide only health education. In this overview, quantitative reviews of prevention and intervention programs targeting adolescent obesity, drug use, smoking, alcohol consumption, and aggressive and violent behaviors such as bullying are presented. Research into the effectiveness of comprehensive school health programs provides evidence of the positive influence of these programs on student health behaviors. However, conditions that initiate and maintain effective school health promotion programs depend on several schools-related organizational and program implementation factors.

Changing Concepts of Health Promotion

According to the WHO, health is defined as more than avoiding illness. Similarly, health promotion involves more than steering people away from unhealthy lifestyles. Health promotion is viewed, according to the Ottawa Charter for Health Promotion (1986), as the process of helping people to increase control over and to improve their health. To reach a state of complete physical, mental, and social well-being, individuals or groups must be able to identify and realize their aspirations, to satisfy needs, and to change or cope with their environment. The Jakarta Declaration on Health Promotion in the 21st Century (1997) presented the principles of equity, empowerment, and participation as central to health promotion practice and outlined priorities for promoting social responsibility for health, increasing investments for health development, increasing community capacity, empowering the individual, and securing an infrastructure for health promotion. However, working with values and principles of health promotion is difficult, because none of these key documents report how to apply and implement these principles in practice. In addition, even though many health promotion models were designed and implemented to evaluate health promotion programs using principles such as empowerment and participation, the realization of these values and principles were not the focus. Currently, the ever-widening gap between rich and poor is an issue of great concern, and compelling evidence confirms that societal and material exclusion is highly linked to health problems. Health inequalities exist in the levels of mortality and morbidity, accidents and injuries, risk behavior, mental health, school achievement, and family violence. Given that American and European children and adolescents in high-risk settings (e.g., low income families, high unemployment of the caregivers, poor neighborhoods) were in poorer health than those living in wealthier settings, the implementation of the principles of equity, empowerment, and participation remains a continuous challenge for future health promotion in schools.

Health-Promoting Programs

In the past two decades, an increasing number of school-based mental health programs and services have been developed and implemented. The development and assessment of school-based health programs is an emerging field with many issues that need to be addressed (Paternite, 2005).

These programs vary with respect to age range, comprehensiveness, theoretical background, and the importance of evaluation. Although some studies comprised primarily survey data, others examined the effect of intervention programs. Several papers incorporate a substantial body of epidemiological and demographic data as basis for their conclusions. Most discuss policy options and recommendations. Thus, substantial variation exists with respect to such factors as level of detail, use of research data, intended audience, and political viewpoint.

In the following sections, some examples of comprehensive programs will be provided, prominent trends will be presented,

and finally frequent domains in health promotion programs will be evaluated.

A prime example is the Child and Adolescent Trial for Cardiovascular Health (CATCH), which is the most comprehensive multilevel program that has been extensively evaluated and disseminated since its development (Hoelscher et al., 2001). The interventions targeted changes at the school level (food services offerings and minutes of class time devoted to physical activity) and at the student level (psychosocial factors, dietary behaviors, physical activity levels, smoking intentions, physiological indicators). CATCH interventions consisted of (1) Eat Smart, a school food service program to provide children with meals reduced in fat and sodium; (2) CATCH physical education, to increase the amount of time students spent in physical activity at school and for other times of the day; (3) Hearty Heart and Friends, 15 classroom lessons to teach dietary and physical activity information through a series of stories; and (4) Family Fun Nights, during which pupils and family members participated in 90 min of games, fitness-related activities, and healthy snacks. The trial demonstrated positive changes in the school food service and physical education program, as well as in students' cardiovascular health behaviors.

Generally, health promotion programs have been confined to highly selective programs designed to identify specific health risks, such as tobacco smoking, alcohol consumption, or drug use, and to train health-promoting behaviors, for example, coping strategies. Most of these programs are designed for late childhood and early adolescence and pursue multiple strategies for preventing health damage, including more traditional strategies (e.g., teaching drug information and general communication and problem-solving skills) and approaches based on the social influence model (which emphasizes strategies for identifying and resisting social pressure to use drugs or alcohol). Time reserved for cognitive instruction was usually brief, with most curricula ranging between 5 and 15 lessons. Although the overall cognitive progress in most programs was impressive, the time provided was not sufficient to produce corresponding reduction in alcohol, drug or nicotine use. Mostly, the effects were stronger and longer lasting for girls than for boys. Frequently, developmentally relevant variables were incorporated; for example, increasing peer pressure or a risky lifestyle during adolescence. Resistance-Skill Training, however, was not always found to be an effective strategy for preventing the onset of alcohol, drug or tobacco use; sometimes counterproductive effects were found.

Health promotion in middle schools is a neglected area, although the middle school years are a time of increasing risk for negative health-related outcomes. Health promotion in the middle school mostly focuses on a social decision approach (e.g., teaching strategies and skills that help children to make favorable decisions when confronted with health damaging situations and offers) and social skills training (in which children are prompted, coached, and guided to practice using the skills). These approaches are based on the observation that children are unlikely to retain and use information conveyed solely through formal lessons; they need opportunities for reinforcement and practice.

Additionally, in recent years, health promotion or health education programs have been developed for elementary school children. For example, innovative methods of engaging and increasing physical activity in children in elementary school have been implemented, examining the effectiveness of an unstructured, moderate to vigorous before-school physical activity program on academic performance (Tompkins et al., 2012).

Recently, the interaction with families of high-risk children became a major focus, particularly in settings outside school. The Triple P Program (Sanders, 2008), for example, aims at helping parents of kindergarten children with sleeping and eating disorders to cope with these challenges by developing positive parenting attitudes and behaviors.

Results of the Healthy Youth Survey in Washington State that assessed school-based health interventions and academic achievement showed strong associations between health risks and academic achievement. Based on 13 key physical and mental health risk factors, the association between health risks and academic performance was bidirectional. Students who performed poorly at school had more health risk factors, which negatively influenced their performance and in turn led to further health risks (Dilley, 2009).

To summarize, health promotion and education programs target early childhood to adolescent students and assess problematic behaviors (that are highly interrelated such as drug and alcohol use) and unhealthy lifestyles (with respect to nutrition and physical activity). The number of programs preventing bullying, violence, and aggression or stress increased during the last decade. Most programs are implemented in educational environments, but preventive approaches sometimes reach out to families with school children at risk.

Evaluation of School-Based Prevention and Intervention Programs

In assessing program outcomes, the following five criteria should be met: (1) the use of appropriate comparison groups; (2) the use of appropriate pretests, posttests, and follow-up assessments; (3) examining research attrition; (4) the validity of dependent variable assessments; and (5) the use of statistical procedures appropriate for program evaluation research. In the following sections, quantitative reviews of prevention and intervention programs targeting adolescent drug use, smoking, alcohol consumption, physical activity, bullying, violence and aggression, and stress are presented. They represent a new approach, because program classification schemes were used to categorize outcomes, which were then employed in a quantitative metaanalysis of study effect sizes based on the criteria listed above.

Metaanalyses of Smoking Prevention Programs

Current estimations show that about one of four adolescents smokes cigarettes on a regular basis. Tobacco-use prevention interventions for adolescents that have been studied can be classified as community-based, school-based, or health care provider-based programs (Krowchuk, 2005). In school environments, interventions can be administered as part of the normal curricula with access to almost all pupils. The frameworks used in implementing these interventions include

inform-and-instruct models, social competence models, social influence models, and combined social competence/social influence models. Rigorous analytic studies confirmed that interventions based on the social influence model showed the greatest effects (Thomas, 2002). Programs based solely on the social competence model are also quite effective in preventing teens from smoking. Increasing knowledge of the adverse effects of smoking does not prevent adolescents from smoking. No evidence could be found that the combination of methods is more effective than social influence alone (Skara and Sussman, 2003). For example, a metaanalysis conducted by Thomas et al. (2013) revealed an average 12% reduction in starting smoking for pure prevention cohorts compared with control groups. Studies reporting change in smoking behavior over time showed no overall effects, but at an intervention level positive findings were found for social competence and combined social competence and social influences interventions.

Effectiveness of Drug Abuse Resistance Education

School-based drug prevention programs have been an integral part of the US and European antidrug campaign. Among the different programs proliferated, Project DARE (Drug Abuse Resistance Education) is the most widely implemented school-based, drug use prevention program in the US, which has been adopted by approximately 50% of school districts nationwide. However, results of a metaanalysis showed that DARE's short-term effectiveness for reducing or preventing drug use behavior is small (Pan and Bai, 2009). Considering the enormous amount of public financial support for DARE, the short-term effectiveness of DARE cannot be regarded as satisfactory (West and O'Neal, 2004).

Effectiveness of Bullying Prevention Programs

Studies showed that bullying in school is seen as a severe problem that concerns one in five school-aged children throughout the whole world. Bullying has recently become an issue of public concern and has also reached the attention of the major media networks. Articles have been featured in several top newspapers and magazines describing cases of children who committed (or attempted) suicide because of bullying. Consequently, school bullying has increasingly become the focus of intervention and evaluation programs in school. Recent metaanalyses have revealed only modest effects of antibullying campaigns (Smith, 2011).

These results are evidence that single-level interventions are not effective. In contrast, multidisciplinary whole-school interventions have been shown to be the most effective in reducing bullying behavior with rate reductions of up to 20% (Ttofi and Farrington, 2012). Baldry and Farrington's (2007) assessment of bullying studies is noteworthy. They reported that about half of the studies had positive outcomes and the other half showed mixed, small, or undesirable effects.

The most effective strategies target those who are bullied, those who bully others, and bystanders to the bullying. Universal intervention programs have that potential (Michaud, 2009). The metaanalysis by Ttofi and Farrington (2012) revealed that the most effective program components for reduction of bullying prevalence rates were videos, disciplinary methods, parent training/meetings, and cooperative group work between professionals.

Effectiveness of Physical Activity Health Promotion Programs

Data from the WHO revealed that 1.9 million deaths worldwide are associated with physical inactivity, and at least 2.6 million deaths are caused by excessive weight or obesity (WHO, 2004). Children and adolescents spend a substantial amount of time in school and lack the free time to engage in physical activity to support their well-being. Consequently, public health agencies must invest in the promotion of physical activity (WHO, 2010).

A Cochrane review by Dobbins et al. (2013) analyzed randomized controlled trials of school-based programs for physical activity and found that the interventions had small effects on physical activity rates, systolic and diastolic blood pressure, body mass index, and pulse rate. In total, school-based physical activity interventions increased the number of children involved in moderate to vigorous physical activity during school hours. In addition, children and adolescents who took part in the program spent more time in moderate to vigorous physical activity (with results across studies ranging from 5 to 45 min more) and spent less time watching television (results range from 5 to 60 min less per day).

Effectiveness of Violence and Aggression Prevention Programs

Violence among adolescents is an important public health problem in the US; the rate of violent crimes averages about 4.2 for every 100 youths between the ages of 12 and 20. Reports from victims revealed that the rate of violent and aggressive acts by youth perpetrators is higher than in any other age group (Maguire and Pastore, 2003).

The Surgeon General's 2001 report on youth violence (U.S. Department of Health and Human Services, 2001) reported a list of school-based violence prevention programs as model or encouraging programs, such as the Seattle Social Development Project, Families and Schools Together (FAST) Track, the PATHS (Promoting Alternative THinking Strategies) curriculum, and I Can Solve Problems. Evaluated school programs focused on topics or skills to reduce aggressive or violent behavior such as emotional self-awareness, emotional control, self-esteem, positive social skills, social problem-solving skills, conflict resolution, and teamwork.

In elementary and middle school, the intervention focus is on disruptive and antisocial behavior and shifts to general violence and specific forms of violence, including dating violence in middle and high school. Results revealed that all strategies (e.g., informational, cognitive/affective, and social skills building) showed a reduction in violent behavior. Universal school-based programs also have additional benefits, such as significant improvements in school attendance and school success. A metaanalysis of school-based programs confirmed and supplemented the *Community Guide* findings (Hahn et al., 2007). However, even single approaches had a mild positive effect on reducing aggressive and violent behavior (Park-Higgerson et al., 2008).

Effectiveness of Stress Prevention Programs

Studies have indicated that children are constantly affected by daily stressors in their daily routines. Their capacity and skills to cope with these stressors were significantly associated with their psychological well-being (Pincus and Friedman, 2004).

Various studies have revealed that children can use coping skills as a buffer or moderator against negative life stressors to maintain psychological well-being. Dysfunctional coping is a highly relevant issue for the development and maintenance of depression, considering that depression is ranked as the fourth leading cause of disease, accounting for almost 12% of disabilities worldwide (Üstün et al., 2004), and its association with dysfunctional psychosocial adaptation over the life span (Myron, 2008). Therefore, the development of adequate coping skills and especially school-based interventions is important. Programs are developed with the aim to teach children specific problem-focused skills to enhance coping. Fewer programs focus on emotion-focused coping strategies, such as how to modify thoughts or feelings, or learning how to manage the demands of a situation (Pincus and Friedman, 2004).

Two programs are presented below as examples of stress and coping prevention intervention that have had positive effects.

The *Rochester Child Resilience Project*, a preventative program, was developed to support coping strategies with the goal of enhancing resilience in urban children (Cowen et al., 1995). In grades 4–6, urban children were taught various skills for coping with life stress. This program consists of 12 sessions. The five variables found that divide between stress-resistant and stress-affected children were perceived global self-worth, realistic control attributions, empathy, social problem-solving skills, and self-esteem. Two sessions consist of teaching children the distinction between solvable and unsolvable problems and the training of specific strategies for coping with unsolvable problems. The third session focuses on identifying feelings in oneself and in others and on teaching the relationship between feelings and life experiences.

Outcome data revealed several positive effects. Learning problems and task-orientation significantly improved. Evidence of additional benefits was also found for overall perceived self-efficacy and for dealing with new and difficult problematic situations. Furthermore, participants had more realistic control expectations for coping with controllable and uncontrollable problems and also reported reduced anxiety (Pincus and Friedman, 2004).

The *I Can Do Program* was developed as a short-term classroom-based program to teach children in general problem-solving and coping skills, to give children practice in utilizing these skills to five specific stressors, to increase efficacy for effective implementation of the coping strategies for each stressor, to enhance children's problem-solving skills in relation to each stressor, and to increase children's knowledge about the stressors. Overall, program results have been positive. Children significantly improved in the effectiveness of their coping solutions even at 5-month follow-up. This program provides promising evidence that supporting children in utilizing specific coping skills can improve efficacy of coping (Pincus and Friedman, 2004).

Implications for School Health Programs and Personnel

The School Health Education Evaluation indicated that for school health education to promote health in children, schools should devote at least 50 h of classroom time each year to health instruction. However, in many industrialized countries, particularly in southern and eastern Europe, these standards are not met (Takanishi and Hamburg, 1997). Limited resources, including curricular time, make it unlikely that health promotion in schools will realistically increase in strength. Thus, developing more efficient ways to promote children's health is essential; for example, by adding complementary interventions to school health education from other sources.

Metaanalyses of more recent school-based studies indicate that carefully evaluating the programs is a necessary part of the improvement process. Overall, improvements of methodology and conceptualization of intervention programs are noticeable, but additional empirical work needs to be conducted to upgrade substandard procedures regarding experimental attrition and to establish the validity of dependent variable measures. Furthermore, the need still exists for developing program intervention models that clearly and fully follow tenets of the guiding theory. Prevention and intervention programs that have been already designed and evaluated are largely confined to certain age groups (often to adolescents) and are limited to the treatment of certain problematic behaviors (such as drug, alcohol, or tobacco use). The health needs of younger ages, for example, preschool children or children from grades 1 to 5, are largely neglected.

Based on the recent developments of health promotion values and principles detailed in the Jakarta Declaration, health promotion in schools should acknowledge societal factors such as inequalities and poverty as important determinants of health in children and adolescents. Health promotion in schools, therefore, must incorporate life quality at the community level when designing programs. School health personnel needs to manage factors that influence children and adolescent health but are beyond the traditional focus of health education and behavior change. They need to assess the quality of life as it is perceived by children and adolescents and identify the specific needs of individual children. Then, community-based action can be developed to address these issues.

Abstract

Health psychology is an area of applied psychological research and a profession. Health psychology research examines the determinants and consequences of physical health, showing that health behaviors are critical to health. Four core topics in health psychology are discussed in this article: (1) the promotion and maintenance of health, (2) prevention and treatment of (chronic) illness, (3) the etiologic and diagnostic correlates of health and illness, and (4) patient behavior in the health care system.

Health psychology is concerned with the study of psychological processes in health, illness, and health care. Health psychologists study behavioral factors associated with staying healthy, and they examine how patients with health problems can be helped to improve their quality of life and well-being. They also examine individuals in experimental research settings, work with groups in real-life settings, or observe interactions taking place between health professionals and patients in a health care setting. Findings from basic research are applied by health psychologists in a variety of settings, ranging from primary care and hospitals to municipal health services and health policy bodies, employing different intervention techniques, such as health education, training, and cognitive-behavioral therapy. Health psychology is a fast growing subdiscipline in psychology and employs theories from personality psychology, social psychology, developmental psychology, and biological psychology to understand and explain how psychological factors impact on health. Specifically, social psychological theories on behavioral regulation have proven important in advancing the field and contributing to why and how people adopt health goals and engage in strategies to achieve these goals (Mann et al., 2013). Similarly, self-regulation models, which have been developed to explain adaptive responses to threats, have been derived in specific formats to explain responses to threatened health goals (De Ridder and De Wit, 2006). These theories draw attention to the difficulties that may arise when individuals have to deal with long-term goals while being occupied with immediate needs that can be at odds with long-term investments in health. These more specific theories have replaced the generic biopsychosocial model (Schwartz, 1982) that was used in earlier work but has proven difficult to inform research and practice.

The term 'health psychology' was first used by Matarazzo in 1980, defining it as "the aggregate of the specific educational, scientific, and professional contributions of the discipline of psychology to the promotion and maintenance of health, the prevention and treatment of illness, and the identification of etiologic and diagnostic correlates of health, illness, and related dysfunction" (p. 815). Health psychology is distinguished from related disciplines such as clinical psychology and behavioral medicine with its focus on physical (rather than mental) health and its orientation on behavioral (rather than medical) aspects of health. Following Matarazzo's definition, the core areas of health psychology are commonly defined as (1) the promotion and maintenance of health, (2) prevention and treatment of (chronic) illness, and (3) the etiologic and diagnostic correlates of health and illness. Another important core area in health psychology has been defined as (4) patient behavior in the health care system.

Promotion and Maintenance of Health

Lifestyle factors that have been identified as relevant for health, such as the holy five of eating, smoking, alcohol use, exercise, and sleep, are an important topic in health psychology. These health behaviors are estimated to account for half of the premature death from the 10 leading causes (most prominently, cardiovascular disease and cancers) in the developed world. While infectious diseases were the leading causes of morbidity and mortality until the first half of the twentieth century, lifestyle-related diseases are now regarded as most contributing to morbidity and mortality. Although many other factors are involved in the development of these diseases, it is recognized that healthier lifestyles are the key to reducing the incidence of these conditions. The concept of health behavior as behaviors that are relevant for health either because they pose a risk to health (e.g., smoking) or because they promote health (e.g., sufficient sleep) was established in the 1960s in a large epidemiological study among 7000 adults living in Alameda County (California, USA), showing that behaviors such as not being physically active, skipping breakfast, or regularly drinking more than five units of alcohol at a single session were predictive of mortality (Belloc, 1973). Health behavior has been defined as "any activity undertaken by a person believing himself to be healthy for the purpose of preventing disease or detecting it at an asymptomatic stage" (Kasl and Cobb, 1966). Importantly, activities that are relevant for health from a medical point of view may not be regarded as such by individuals. Individuals smoke because they consider it relaxing or they eat fatty foods because they appreciate their taste – they do not necessarily engage in these behaviors because they want to behave unhealthily. In a similar vein,

people may engage in health-promoting activities for other reasons than a concern about their health and, for example, exercise because they enjoy the fun of being physically active. One particularly important issue in health behavior research is to better understand the factors associated with people's nonengagement in behaviors that are beneficial to their health. Even when people have a genuine desire to stay healthy, they often do not display the behavior that is required to achieve their health goals. The 'intention behavior gap' (Sheeran, 2001) has become a widely known concept to explain why people may have the intent to be healthy but most of the time face serious difficulties in engaging in that behavior for a variety of reasons, such as underestimating the effort that is associated with acting upon one's intentions, lack of planning the activities that are required for acting, or forgetting to act when one is occupied with other activities. It should be noted that the concept of health behavior is fluid and the activities that are included may vary as a function of medical knowledge. For example, the use of a condom when having sex with a person whose sexual history is unknown only emerged as a preventive health behavior after the human immunodeficiency virus/acquired immune deficiency syndrome (AIDS) epidemic in the 1980s. Apart from the classic five health behaviors named previously (eating, smoking, alcohol use, exercise, and sleep), nowadays safe sexual behavior, using sunscreen, driving sensibly, using a seat belt, and dental behaviors are also regarded as relevant for health, but this may change as medical knowledge evolves.

Health behaviors have been studied mainly from the perspective of social-cognitive models, such as the health belief model and the theory of planned behavior, highlighting the beliefs that individuals hold about the outcomes of their action as key determinants of health behavior (Armitage and Conner, 2000). These beliefs are thought of as relatively stable characteristics that have the potential to influence behavior while being amenable to change. The models that have been used are based on the expectancy–value principle: the expectancy that a given action will lead to a specific outcome and the value that is attached to that outcome. These models thus highlight that individuals engage in deliberate rational decision making about several options. The most widely used social-cognitive model is the theory of planned behavior that has gained considerable empirical support, although explaining intention to engage in health behavior (39% of the variance in intention) has proven easier than predicting actual health behavior (21% in case of objective reports and 31% in case of subjective reports) (Armitage and Conner, 2001). Research in social-cognitive models has resulted in interventions (e.g., education and training in primary care setting) employing persuasive communication strategies to change health beliefs, mostly with disappointing results. Several effective intervention strategies exist that help people to formulate intentions to change their health behavior, whereas strategies aimed at supporting people to enact their intentions have witnessed modest results, even when information was tailored to the specific needs of people depending on the stage of change they were in (Weinstein et al., 1998). A particular successful exception are interventions that employ implementation intentions (Gollwitzer, 1999) that specify when, where, and how the intended behavior should be performed by employing an if–then plan, increasing the chance that people will recognize the opportunities for action, which they may otherwise forget when they experience a momentary drop in their motivation for action. New generations of models of health behavior have departed from social cognition models and reflect that health behavior is not always rational and deliberate but rather governed by habits, impulses, or emotions (Hofmann et al., 2008). To date, these novel approaches recognize that interventions aimed at improving health behavior should take account of the very nature of health behavior and implement strategies that do not require a lot of effort to support people who do not have sufficient resources to change their behavior in the desired direction (Marteau et al., 2012). Regardless of the different approaches that are typically used, health promotion in behavioral models pertains to primary prevention of any type of illness that may result from engaging in these risky health behaviors and thus pertains to "maneuvers that reduce the chances that a health problem will ever develop" (Kaplan, 2000: p. 382).

Prevention and Treatment of (Chronic) Illness

Prevention and treatment of specific illness has some overlap with the first area but obviously focuses on people who have been identified to be at risk for disease (for example, those who are at risk for breast cancer as the result of screening programs involving mammography) or who have been diagnosed with chronic illness (for example, rheumatoid arthritis). Here, the aim is to detect risk of disease at an early enough stage in order to eliminate or slow down its development or, in case of already diagnosed illness, to promote adjustment to disease.

With regard to the former, screening programs (secondary prevention) take the form of health checks, such as measuring weight, blood pressure, carrying out cervical smears, and offering genetic tests for illness such as Huntington's disease and some forms of cancer. Three broad types of screening exist: opportunistic screening (using the time when a patient visits medical services for a particular reason), population screening (which involves the systematic examination of potential health problems in large community surveys), and self-screening (encouraging people to practice self-examination of, for example, breasts and testes, or buy over-the-counter kits to measure blood sugar levels or cholesterol). The aim of all screening programs is to detect a problem at the asymptomatic stage in order to offer medical treatment as early as possible. Although there exists enthusiasm for screening as a prevention strategy, there are ethical considerations as well as issues of cost-effectiveness and the psychological consequences of screening for individuals (Shaw et al., 1999). For health psychology, the effects of screening on the psychological state of individuals are most relevant. For example, receiving a negative result (i.e., not having the condition tested for) may create a false sense of reassurance while receiving a positive result (i.e., having the condition tested for) may lead to elevated levels of anxiety. Most studies in this area have shown that stress and negative effect resulting from receiving a diagnosis disappear after a short while. In addition, health psychologists study the factors that predict uptake of screening among the population, which has demonstrated considerable variety relating to health beliefs, risk perception, and feelings of

being able to do something about one's own health. Studies on perceived risk and related concepts such as perceived vulnerability refer to subjective estimates of the likelihood of personally contracting a disease and have proven a more powerful predictor of screening uptake than the perceived (serious) consequences of disease (Weinstein and Klein, 1995). Message framing (i.e., presenting health risk information as gains vs presenting it as losses) has proven an important moderator of how the general public responds to testing for health risks (Rothman and Salovey, 1997).

There is an extensive literature on the theoretical and empirical foundations of coping and adjustment in chronic illness. It is estimated that at any given moment, about 50% of the population suffers from chronic illness requiring some form of medical intervention (Taylor and Aspinwall, 1996). These patients face adaptive tasks that require them to come to terms with the disease-related changes, such as dealing with pain and incapacity, preserving an emotional balance, sustaining relationships with family and friends, and preparing for an uncertain future (Bensing et al., 2002). Coping is a response to the experience of such adaptive tasks and consists of three stages (Lazarus and Folkman, 1984): an event appraisal of what is at stake, an appraisal of one's personal and social resources to deal with the task, and the behavioral or emotional coping response aimed at either resolving the problem (problem-focused coping) or one's emotional reaction to the problem (emotion-focused coping). Research on coping strategies has met with some methodological challenges and effects of coping as studied by omnibus questionnaires have been relatively modest. Nevertheless, the coping concept is immensely popular among health professional involved in the design of interventions to help people adjust to their chronic condition (De Ridder and Schreurs, 2001). While most research has focused on problem-focused coping as a means to adjust to (chronic) illness, emotion-focused coping has demonstrated favorable results on adjustment. Specifically, expression (rather than inhibition) of emotions and benefit finding in adverse events as specific forms of emotion-focused coping have shown impressive results (De Ridder et al., 2008; Stanton et al., 2000). Another issue deserving discussion has to do with the kind of outcome measures that health psychologists employ as dependent variables in the studies examining effects of psychological interventions. A typical measure derived from medical practice is to determine the level of adjustment by health-related quality of life, defined as measures of daily functioning and assessed by the widely used Rand 36-Item Health Survey (Van der Zee et al., 1996). Such functional measures of mental, physical, and social functioning are relevant in the context of medical treatment but have proven to be unrelated to psychological measures of adjustment, such as satisfaction with life or well-being (Taylor and Aspinwall, 1996). The basic assumption of psychological theories is that the successful pursuit of meaningful goals plays an important role in well-being (Ditto et al., 1996). Therefore, several researchers in the field of quality-of-life studies have emphasized the role of personal goals and related constructs in patient perception of quality of life. Highlighting this perspective may also account for the finding that many patients with chronic illness report positive adjustment (De Ridder et al., 2008).

Etiologic and Diagnostic Correlates of Health and Illness

Early research in the 1950s on psychological factors in chronic illness has been characterized by a strong desire to identify personality factors, which would explain why some individuals run a greater risk of becoming ill than others. In an attempt to link psychological factors to the onset of disease, research was based on the assumption that a specific psychological makeup would be predictive of disease. A typical example is the type A personality with a proneness to coronary artery disease whose behavior is characterized by competitive drive, impatience, and hostility (Booth-Kewley and Friedman, 1987). Nowadays, such strong views on the role of personality and psychological factors in the etiology of (specific) disease are no longer maintained. Rather, recent research emphasizes the role of psychological factors in (dealing with) stress and emotions. The experience of psychophysiological arousal (stress) and related negative mood is the result of exposure to stressors that have been defined as any event or condition that is demanding or challenging. Typical categories of stressors are calamitous events (e.g., natural disasters), major life events (e.g., bereavement), daily hassles, and chronic stress conditions (e.g., occupational stress) that are evaluated as threatening and potentially harmful and thus requiring some adaptive response. Acute stressors may challenge the cardiovascular, neuroendocrine, and immunological systems, whereas acute stress in general does not strain these systems as does chronic stress. The most commonly held view of the link between stress and illness suggests that stress leads to disease due to a prolonged interaction of physiological, behavioral, and psychological factors. The 'stress–diathesis' model (Levi, 1974) posits that the wear and tear caused by stress can explain the accumulative damage to the cardiovascular system and other systems of the body. Stress has been mostly studied in the context of coronary heart disease, but there are also studies exploring links between stress and illnesses such as cancer, diabetes, rheumatoid arthritis, and AIDS. Research has been devoted to studying the impact of stress on sympathetic activation (e.g., increased blood pressure and irregular heartbeats via the prolonged production of (nor)adrenaline), which may lead to increased chances of heart disease and infectious diseases, and hypothalamic–pituitary–adrenocortical activation (e.g., cortisol), which may lead to decreased immune function. In addition to these direct effects of stress on health, research has also explored the indirect impact via health-threatening behaviors such as smoking and alcohol abuse, which are also related to the experience of stress. Current stress models consider a wide variety of responses to stress, including mood, behavior, problem solving, motivation to achieve (health) goals, and engagement in health-protective behavior. These wide-ranging effects of stress illustrate the importance of examining the effects of stress on the whole organism rather than focusing on one system only. Responses across all systems work in concert to help the individual adapt by either altering the situation or accommodating its effects. However, chronic activation of these response systems may make individuals more susceptible to negative physical health outcomes at any point in the disease process: onset, progression, treatment, recovery, or recurrence. Despite the impressive effects of stress

on health, there is considerable individual variability in the stress–illness link caused by individual differences in stress reactivity and stress recovery, as well as ways of coping with stress. Negative effects of stress on health become manifest when coping and other resources are not sufficient to overcome stressful conditions. Uncontrollable stress appears more difficult to handle than controllable and predictable periods of threat or demand. An important moderator of the impact of stress on health is social support. In addition to health-protective effects of being integrated in social networks (i.e., through marriage, children, or friends), social support research has identified stress-buffering effects of supportive relationships especially when they provide emotional support. A consistent finding reported in the literature is that social support is related to better cardiovascular functioning and better immune responses (Uchino et al., 1996). Also, strategies for dealing with negative emotions have attracted considerable attention as moderators of the stress–illness relationship. There is accumulating evidence that repression or inhibition of negative emotions may be a risk factor in the onset and course of disease. Although the exact psychophysiological mechanisms involved are still unclear, it has been suggested that the inhibition of emotions may result in increased physiological activity. Denial and nonexpression of emotions can be a useful initial coping strategy to deal with the stress of disease; failure to acknowledge and express emotions can leave these emotions unresolved with chronic raised activity of the sympathetic nervous system as a result. The inhibition of emotions can also delay help-seeking behavior or compromise communication with health care providers. In contrast, the regulated (rather than uncontrolled) expression of negative emotions has demonstrated impressive effects on health. A typical example is the disclosure of emotions paradigm by talking or writing about one's emotions (Smyth, 1998). Talking or writing about emotions is believed to make the emotional experience less invasive, increase insight into why emotions are experienced, and restore psychophysiological balance (De Ridder et al., 2008).

Patient Behavior in the Health Care System

Once an individual gets ill, he or she enters the health care system. Health psychology examines a variety of topics that are related to patients using health services, such as symptom recognition and the decision to seek help, the interaction between patients and health professionals, and adherence to treatment regimens. It is estimated that over 50% of the population experiences symptoms of ill health over any 2-week period. Only a minority of these people seek help from health professionals, depending on how symptoms are perceived and interpreted. Research on symptom perception has been informed by the seminal work of Leventhal (Leventhal et al., 1984), distinguishing between five beliefs about symptoms, which influence subsequent action (identity, cause, consequences, timeline, and control and treatment effectiveness). This and other research suggest that beliefs about symptoms and emotional responses to symptoms more strongly affect the decision to consult medical professionals than the mere experience of symptoms themselves. Depending on the beliefs individuals hold, they may either delay help seeking for reasons of wanting to avoid potentially negative outcomes (blunting) or, alternatively, may use health services for reasons of wanting to be reassured (monitoring). Although beliefs of patients play an important role in shaping their expectancies when seeking medical help, in the past decades, the role of medical professionals has also proven to be important in affecting patient behavior. In general, studies on patient–provider communication show that doctors' communication skills have the capacity to affect patient understanding and satisfaction, adherence, and health outcomes. Consequently, the success and cost-effectiveness of health care services depends critically on the way doctors interact with patients. Models of doctor–patient relationships have identified several important factors that contribute to successful interaction, such as doctors appreciating patients' dual need to know and understand and to feel known and understood (Engel, 1977). Doctor–patient interaction models have promoted new approaches to medical decision making, such as shared decision making, involving the patient to a greater extent in what kind of treatment is required. These new approaches have contributed to better patient understanding of their medical condition and better patient recall of the information given during medical encounters. Both factors are important in increasing patient adherence to treatment regimens, which is generally low with estimates of about 50% in medication adherence and even lower in behavioral recommendations. Not following advice given by health care professionals has even been observed when nonadherence can be life-threatening (e.g., medication use after organ transplantation). Low adherence has wide implications for patients' health (e.g., unnecessary complications), population health (e.g., antimicrobial resistance in case of interrupted use of antibiotics), and health care cost-effectiveness (e.g., nonused medicines). Despite the magnitude of the problem, it has proven difficult to pinpoint the causes of nonadherence in terms of patient or provider characteristics or health care system characteristics. New promising avenues for adherence research relate to the identification of patterns of adherence, distinguishing between failure to participate in the regimen altogether, to variability in regimen conduct, or to timing errors (e.g., because of cognitive impairments in prospective memory). Moreover, it has been proposed that medical professionals should seek collaboration with patients about the best way of treatment rather than instructing them what to do. It has even been proposed that the term 'adherence' should be replaced by 'concordance' as an expression of mutual agreement about treatment between patient and health care provider. These developments align with the growing importance of self-management in illness treatment, highlighting the need for health professionals to motivate and support patients to take care of health themselves by, for example, feeling responsible for treatment on a day-to-day basis (De Ridder et al., 2008). Psychological research examines in what way doctors can communicate with patients in ways that help them to manage their illness by empowering patients to actively participate in the consultation. The importance of the patient's role is also demonstrated in research on placebo effects (health gains observed following administration of inert interventions), which can be explained by patient expectations and

anxiety reduction. Psychological research has demonstrated that stress reduction based on positive expectations of treatment efficacy and trust in a competent physician provides a powerful explanation of placebo effects.

Concluding Remarks

Health psychology research can reveal psychological processes underpinning health and illness and thereby suggest changes in health care practices designed to optimize effectiveness. Central to health psychology is the concept of health behavior, which plays a major role in health promotion, prevention of illness, illness onset, and patient behavior in a treatment setting via physiological and psychological pathways. New models of health behavior and health behavior change are being developed, moving beyond the traditional models emphasizing rational deliberate decision making about engaging in health behavior, raising several new important questions about its impulsive and automatic nature that need to be answered in future research. One particular issue deserving attention from this novel perspective is how people maintain their initial changes for health behavior and how environmental changes can be implemented that support individuals in behaving healthily. In addition, societal changes pose new questions about health behavior change, such as health behavior in the elderly and cultural issues related to health behavior in an ethnically diverse population. Answers to these questions should be informed by rigorous scientific evidence and academic debate among health psychologists working in a variety of health care practices.

Health Psychology in Childhood

Abstract

Within the field of Health Psychology, children have been rather neglected for quite sometime. Nevertheless, childhood is seen as a crucial phase of life for the establishment of stable health-relevant behaviors, and accordingly many prevention programs focus on this age group. The necessity as well as the urgency of establishing the field of 'Child Health Psychology' is emphasized even more by the fact that children's health risks have increased over the past decades.

Child Health Psychology includes an explicit consideration of developmental aspects, as not only health threats and everyday challenges change with age, but also the scope of action and the determinants of health behavior. Development-oriented Health Psychology needs to consider biological, psychological, and social changes to develop appropriate concepts for prevention and intervention.

Child Health Psychology – An Emerging New Interdisciplinary Field

Child Health Psychology is a young developing field within Health Psychology. Maddux and colleagues are considered pioneers in the area, who in 1986 called for a developmental approach to Health Psychology, especially in childhood and adolescence. This demand is justified by many factors, including the following most important ones:

- Childhood is characterized by various pronounced cognitive, physical, emotional, and social developmental processes. These processes influence a child's understanding of health and health behavior, as well as the possibilities for assuming personal responsibility.
- Parents play a pivotal role in establishing health behaviors. Child health psychology is therefore inseparably intertwined with health-related cognitions and behaviors of parents in a number of ways: First, parents serve as models for their children; second, they build the framework for the child's health beliefs; and third, they often decide for their children. With increasing age, the child's microsystem widens and other protagonists (like peers and teachers) gain in influence.
- Health Psychology focuses explicitly on prevention and health promotion. Many health-relevant behaviors are formed in childhood and remain stable into adulthood. To prevent unfavorable developments and promote adequate behaviors, intervention efforts must take place very early and include the relevant actors (depending on the child's age) to achieve sustainable effects.
- Health challenges change over the course of development and certain diseases manifest in childhood for the first time. Manifestations of chronic health problems may hinder or accelerate the development process. Moreover, health-related behavior itself is an ongoing process of change (from initiating a new behavior to stabilizing that behavior).
- For ethical reasons it is increasingly accepted that children are entitled to an appropriate explanation of treatment options and should be actively included in decision-making processes.

Hence, Child Health Psychology is an interdisciplinary basic and applied research field that addresses questions of health and illness. In this context, the focus is inevitably on the role of the family. In basic research, the determinants of child health behavior from an ecosystem/familial perspective, the psychological consequences of chronic illnesses, and the development of concepts of health and illness are examined. Applied research is based on two particularities: On the one hand, the need for development-appropriate concepts (in relation to didactics as well as to content, inclusion of the family); on the other hand, a strong focus on prevention. In this context, Child Health Psychology overlaps with the fields of Clinical Child Psychology and Pediatric Psychology. Nevertheless, while Clinical Child Psychology focuses mainly on mental disorders and their treatment, Pediatric Psychology is mainly concerned with chronic physical diseases and secondary prevention. In addition, commonalities can be found with the interdisciplinary field of developmental psychopathology that studies the onset and course of mental disorders over a lifetime. One last distinction needs to be made: The term 'Child Health Psychology' is often used for all minors, including adolescents and young adults (up to 18/21 years of age). As issues of adolescence are addressed elsewhere in this volume, this article will, in accordance with established classifications in developmental psychology, focus on the age range from birth to 12 years. However, this is not a universal, inflexible age limit: As a result of the increasingly more common acceleration of especially physical maturation processes, so-called adolescent risk behaviors (e.g., smoking, drinking, and dieting) can be found increasingly more often among younger children as well.

Developmental Tasks and Competences in Childhood

No other period of life is associated with changes as obvious as childhood. These changes are not only physical, but also emotional, social, and cognitive in nature. The concept of 'developmental tasks' describes universal, normative requirements that certain age groups face and the competences they gain. The developmental context (e.g., culture) influences rather the precise degree and timing of the developmental tasks.

Table 1 Developmental milestones according to Havighurst (1971)

Age	*Developmental milestones*
Birth to 6 years	● *Body*: Sitting – crawling – standing up – walking – learning to control the body and its wastes ● *Food*: Making the transition from liquid to solid food and from being fed to eating independently ● *Cognition*: Forming concepts about the social and physical reality (e.g., sex differences, physical laws, etc.) – preparing to learn reading ● *Interaction*: Talking – perspective taking – joint attention
6–12 years	● *Body*: Refinement of physical skills – developing healthy behaviors ● *Cognition*: Learning social roles – developing values, moral attitudes and conscience – refinement of concepts ● *Interaction*: Establishing friendships – becoming more and more independent from parents – developing positions toward social groups and institutions

Havighurst (1971) distinguishes between six major phases of development. For childhood, the first two phases, 'infancy and early childhood' (birth to 6 years) and 'middle childhood' (6–12 years) are relevant. **Table 1** lists the respective requirements and competences. The successful accomplishment of these requirements is crucial for further development. The establishment of health-related behaviors is listed as one of the developmental tasks for the 6- to 12-year age group.

Not only do the requirements change but also the possibilities to deal with these requirements. Coping in this context is understood as the use of self-regulatory competences (emotional, motivational, attentional, behavioral, cognitive, social processes) under stress and how these systems work together (Skinner and Zimmer-Gembeck, 2007). There is a broad research consensus on normal age-graded shifts in coping strategies: In infancy, mainly reflexes can be observed, while at preschool age direct actions are important; in middle childhood, cognitive strategies occur. It seems as though it is not the precise function of strategies that changes but rather their phenomenology. Thus, children of different ages mostly use the search for *support*, *problem solving* (including action), *escape*, and *distraction* coping strategies to deal with difficult situations. As the child grows older the strategies become more differentiated and their use more context-specific. Coping strategies are shaped not only by the child's individual characteristics (e.g., developmental stage, temperament), but also by the social context, which means, in childhood, mostly the parents or legal guardians/carers. Modeling/observation, parental practices and the emotional climate in the family are considered important influences.

Children's Concepts of Health and Illness

Impressive developmental changes can be observed, for example, in the context of concepts of health and illness. Piaget's approach to cognitive development is mostly used for the explanation of this idea, which postulates an association between general cognitive development and the development of health- and illness-related concepts. While this approach has met with some opposition, there is general consensus that beliefs about health and illness become more and more differentiated with children growing older, in relation to symptoms as well as to their interaction, the cause and course of illness, and treatment options (**Table 2**). In addition to children's developmental stage, their experiences with (chronic) illnesses as well as social influences (e.g., parental illness concepts) are discussed as distinctive influences on children's illness concepts (Lohaus, 2013).

Concepts of illness play an important role in coping with a disease. According to Leventhal's Common-Sense Model (Leventhal et al., 1980), people develop an organized set of subjective beliefs that guide their further actions when dealing with health threats. Especially control beliefs in relation to

Table 2 Developmental stages of illness concepts according to Biface and Walsh (1980; see Lohaus, 2013)

Stage	*Description*
I. Prelogical explanations (2–6 years)	
1. Phenomenistic	● The cause of illness is an external phenomenon which can cooccur while being temporally and spatially remote.
2. Contagion	● The cause of illness lies in things/people around the child that are close to the child but do not touch him/her. The connection happens via proximity or magic.
II. Concrete logical explanations (7–10 years)	
3. Contamination	● Distinction between cause and effect: The cause is a person, object or action outside of the child that is harmful for the body. ● The illness is caused by touching the person or object or by a dangerous action of the child.
4. Internalization	● The disease is located inside the body while the real cause (person, object) may be outside of it. The connection happens via internalization (e.g., inhaling the object). ● Illness is still a vague concept, inaccuracies occur (e.g., in relation to organs and functions).
III. Formal logical explanations (≥11 years)	
5. Physiological	● The cause of illness is seen in specific internal physiological structures and functions and can be evoked by external incidents. The cause is described as a malfunction of an inner organ or as a process of internal events culminating in illness.
6. Psychophysiological	● Illness is seen as an internal physiological process, but additional or alternative psychological causes are appreciated: It is acknowledged that inner processes like thoughts and emotions can influence bodily functions.

treatment show a consistent association with a child's self-management (Law et al., 2012). Prevention and intervention strategies should, therefore, take into account children's concepts of health and illness (and particularly their perceived controllability).

Theories of Health-Related Behaviors in Childhood and Adolescence

In Health Psychology, a plethora of models exists to explain and predict individuals' health behaviors. Most of these models are adopted from social and motivational approaches and focus on personal beliefs, intentions, and motives. These models have been developed and tested for adults and then transferred to childhood. However, to use models for children that have been developed for adults seems to be inappropriate as children are dependent on their parents' beliefs, behaviors, and decisions in many health issues (e.g., vaccination, consultations, but also health-protective behaviors like dental care). Therefore, studies often investigate parental beliefs and their influence on decisions (e.g., participation in vaccinations). In recent years, self-regulation has been demonstrated to play an important role in Health Psychology. Many health-related behaviors like eating or physical activity imply resisting habits or temptations to achieve a goal in the future. Given these considerable barriers, self-regulation theory focuses on the ways in which individuals direct and monitor their emotions and actions to achieve their (long-term) goals. Self-regulation competences involve different skills, such as regulating one's emotions, inhibiting impulses, maintaining attention, and setting or pursuing long-term goals. Self-regulation is a genuine developmental concept, since self-regulatory competences differ not only interindividually but also intraindividually. From a developmental perspective, the first 5 years of life are seen as the most important period in acquiring self-regulatory skills and the growth of these skills is a cornerstone of early child development. Social influences such as parent–child interactions are important for shaping these skills as well (Best and Miller, 2010). Studies have illustrated not only the relevance of self-regulatory skills for current health behaviors but also their significance as a predictor of morbidity and mortality in adulthood (e.g., Moffitt et al., 2011). The emergence of self-regulation theories in health psychology opens up new perspectives for development-sensitive health theories, especially for younger children.

For a comprehensive consideration of children's social context, the ecological systemic approach is often used as a theoretical framework for the design of prevention and intervention programs. Bronfenbrenner (1994) views development in terms of different social contexts and their interaction with the individual. He divides the ecological system surrounding a person into five different systems: On the microsystem level (i.e., the level of the immediate environment and its interaction with the child), parents in particular (including parenting style, health beliefs, beliefs about the child's knowledge and behavior) have to be considered. Other important settings are school and child care. On the mesosystem level, interactions between these systems are described (e.g., parents and school). The exosystem includes contexts in which the child is not directly involved but which influence the child's development nevertheless. Here, the parents' place of work or circle of friends are examples, as they codetermine, for instance, the parents' temporal resources although the child has no direct influence on them. The macrosystem refers to the norms, traditions, rules, and laws of a society. At this level the media affect, for example, the popularity of foods via advertisements. To allow for developmental changes, Bronfenbrenner introduces the chronosystem describing the temporal dimension of development with normative (e.g., school enrollment) and nonnormative (e.g., chronic illness) events and their influence on a child's development. Refining his model, and in addition to the aforementioned contexts, Bronfenbrenner later addresses the issues of personal variables (a child's characteristics, e.g., age, gender, preferences, genetic predispositions) as well as of proximal (e.g., parent–child interaction) and distal (e.g., family structure, social, and ethnic background) processes as engines of development.

For Child Health Psychology, mainly the social context and its interaction with the child and proximal processes like the parent–child interaction are important. In the sense of a 'meta-health theory,' that is, the concept that parents have an organized set of beliefs, thoughts, and feelings about their own and their child's health and health-relevant behaviors, the interdependencies between children and parents should be considered. For example, the parental perception of the health risks associated with being overweight influences their willingness to participate in prevention programs (Warschburger and Kröller, 2012). In summary, models integrating the child's socioeconomic context (and here mainly the parental influences) along with their developmental stage are still lacking.

Figure 1 illustrates the draft of an integrative approach considering the most important institutions of socialization in childhood as well as a development-oriented view.

Children's Health Status

Childhood is seen as the period of life with the best health status. Nearly 80% of all children between 11 and 15 years rate their health as excellent or very good. With increasing age and lower socioeconomic status, the percentage of children rating their health negatively increases. Additionally, gender differences become more pronounced with increasing age and especially older girls rate their health more negatively and report more health issues than boys of the same age (Currie et al., 2012). This is in accordance with data on health-related quality of life of children. The importance of the family environment can be observed as well: children from families with higher educational background and better financial resources report a higher quality of life (von Rueden et al., 2006).

In childhood, acute illnesses still top the list of health problems with manifold causes of illness. Most common are respiratory infections (like episodes of the common cold, bronchitis, and tonsillitis) and gastrointestinal infections. Communicable childhood diseases like pertussis, measles, mumps, rubella, or scarlet fever play a minor role. Chronic physical illnesses can be found less often in children than in adults, yet still 15–20% of all children are concerned (Kamtsiuris et al., 2007). In a German representative sample, the most prevalent chronic conditions were overweight and obesity (14.8%), obstructive bronchitis

(13.3%), atopic dermatitis (13.2%), hay fever (10.7%), scoliosis (5.2%), and asthma (4.7%) (Kamtsiuris et al., 2007; Kurth and Schaffrath-Rosario, 2010). For some chronic physical illnesses, a pronounced increase in prevalence rates over the past decades has been observed (Roberts, 2003). In addition to physical conditions, the comparatively high rate of mental problems in childhood must be noted, with attention-deficit hyperactivity disorder, mood disorders, and conduct disorders ranking first (Merikangas et al., 2010).

The increasing importance of chronic illnesses can also be observed when looking at mortality data (cf **Table 3**). Given the improved treatment methods of the past century, acute infections play a minor role, while external causes (e.g., traffic accidents, suicides) as well as chronic illnesses (e.g., cancer) come to the fore.

Prevention and Health Promotion

Childhood is considered the phase of life in which health-relevant behaviors are established and then often maintained into adulthood. A balanced diet and regular physical activity, for example, not only contribute to increased well-being, but also help to prevent various diseases (e.g., diabetes and obesity). These important health behaviors are, therefore, discussed in more detail in the following.

Children's Dietary Behavior

The course for the formation of food preferences and healthy nutrition is set already during pregnancy and breast-feeding. The composition of the mother's diet affects the baby's taste preferences (Mennella et al., 2001). Furthermore, certain taste preferences like those for sweetness (as a sign of energy-dense food) and the aversion to bitter tastes (as a potential sign for toxic substances) are congenital. While it is assumed that babies dispose of an excellent physiological control of food intake, learning processes become more and more important with increasing age. For example, children develop taste preferences via repeated exposure as well as via model (parents, peers, media) or associative learning (e.g., food as a gratification strategy). Not only taste preferences but also knowledge, social norms, and attitudes regulating dietary

intake are shaped on the basis of positive sensory and affective experiences. Here, psychological processes play an important role (Ogden, 2010). Parents try to influence their child's dietary behavior in many different ways. On the one hand, in a very direct way by offering or prohibiting certain foods themselves; on the other hand, in a more indirect way by eating certain foods. In this context, home availability and accessibility, parental modeling and parents' own intake as well as family rules and parental encouragement proved to be positively associated with children's fruit and vegetable consumption. These associations were especially strong in childhood up to 12 years, while the parental influence decreased in adolescence. Moreover, the entire parenting context is important as well: children whose parents used an authoritative parenting style consumed more healthy foods (Warschburger, 2011).

In terms of food intake, a trend toward less healthy eating choices (with the exception of sweets) can be noticed with increasing age: fruits and vegetables are consumed less often while soft drinks, meat, and fast food are consumed more often. While 60% of all children from 3 to 6 years of age eat fresh fruit at least on a daily basis, this proportion decreases to 40% (boys) and 50% (girls) at the age of 11–13 years. These numbers are considerably lower than nutrition guidelines advise and emphasize the deficiencies in children's dietary behaviors already present (Mensink et al., 2007). Not only the choice of foods changes over time, but also specific eating behaviors (e.g., emotional or restrictive eating). With increasing age, the percentage of emotional eating behaviors and the prevalence of weight and figure concerns increases as well. While in infancy mostly feeding disorders can be observed, school children show avoidant, selective, and restrictive eating behaviors and in adolescence 'classical eating disorders' like anorexia and bulimia nervosa come to the fore. Recent longitudinal studies show that, despite the changes in the phenomenology of problematic eating behaviors, a considerable stability can be assumed (Ogden, 2010).

Physical Activity

Sufficient physical activity is considered essential for a child's development and physical and mental health. Physical activity is defined as any sort of bodily movement generated by muscular activity above the normal energy demand. This includes leisure activities (like rollicking or catch games), daily activities (like helping in the garden or on the way to school) but also exercise with performance and competition aspects. The World Health Organization (2011) recommends 60 min of daily physical activity at moderate or vigorous intensity for children over 5 years of age. For younger children, up to 2 h of daily physical activity in the form of active games are recommended.

Traditionally, childhood is seen as a phase of life with a high level of physical activity. However, the precise level of physical activity in children is difficult to measure due to rapid and frequent changes between activity and inactivity. According to national representative data, three-quarters of all children 3–10 years of age get daily exercise and one-third at least three times a week – without considering the physical activity occurring in daily life. However, this quite positive picture changes for the worse with increasing age, especially when entering adolescence. Only 15.3% of all children between 4 and 17 years fulfill the WHO recommendations for physical activity; at 29.2% the prevalence among children 4–10 years old is much higher compared with the 8.9% among 11- to 13-year-old children (Krug et al., 2012). The low prevalence of physical activity is of high relevance for health issues, as a high rank stability of the degree of physical activity from childhood to adulthood can be found (Craggs et al., 2011).

What factors affect the amount of physical activity children engage in? The correlates are manifold and the results inconclusive. As already discussed for dietary behavior, parents play a key role in children up to 12 years with parental model behaviors and parental support influencing the child's activity level moderately; from adolescence on, this influence is

negligible. In addition, the school environment, neighborhood characteristics, and traffic safety prove to be relevant too (de Vet et al., 2011). At an individual level, self-efficacy is correlated with a lesser decline of physical activity with increasing age (Craggs et al., 2011).

Prevention Programs

These results emphasize the fact that already in childhood a high percentage of children show unhealthy dietary and physical activity patterns and, therefore, carry a higher risk for the development of health problems. Especially the stability of these behaviors highlight the fact that childhood is a very favorable time to establish primary prevention programs and to prevent stable undesirable progress. Universal approaches to promoting health in the general population take place in settings like school or day care. As indexed (e.g., children of overweight parents) or selective (e.g., overweight children) approaches, they address selected risk groups. The line up of methods is broad and ranges from structural/environmental (e.g., providing drinking water, rearranging the school yard) to behavioral prevention (e.g., food education). Reviews and meta-analyses emphasize the effectiveness of prevention concepts related to nutrition, physical activity, or both in preventing childhood obesity. In addition, it is important to include the school context (e.g., availability and supply of food in vending machines) as well as parental influence. Furthermore, the bidirectional influences in the parent–child relationship when realizing a healthy way of life should be considered (Waters et al., 2012). In other health areas like prevention of substance abuse or mental disorders, positive effects of prevention programs in childhood and adolescents can be achieved, while success rates vary depending on the extent of the program, the target behavior, the integrated methods, and the age of the children included (Carr, 2002). Key elements for effective prevention programs include a comprehensive approach considering all relevant contexts and starting points as well as an extensive, didactically multifaceted, and age-appropriate program with a focus on strengthening positive parent–child and peer relationships (Nation et al., 2003).

Coping with Chronic Illnesses

Despite the overall excellent health status of children, a considerable percentage of children suffer from chronic disease. A number of chronic illnesses have their incidence peak in childhood (e.g., atopic dermatitis, asthma, tumors of the central nervous system, and functional abdominal pain). Diseases are considered chronic if they last for at least 1 year and lead to functional impairments like repeated consultations or hospitalizations, dependence on regular treatments or impairments in daily activities. Hence, coping with the disease and treatment demands become important (biopsychosocial view).

Chronic childhood illness is often considered a nonnormative, additional stressor in the living environment of the whole family. Thus, chronic illness can not only negatively affect the accomplishment of childhood developmental tasks (e.g., becoming more independent from parents, building relationships to peers), but can also impose – as already mentioned – disease-specific demands like adhering to preventive and curative therapeutic regimes (e.g., avoiding certain environments, regular treatment), confrontation with a potentially reduced life expectancy and the integration of the disease into the self. Chronic illnesses, therefore, pose grave demands on the coping competences of children and their families. While results from many empirical studies suggest that children and families cope astonishingly well with these additional demands, chronic illnesses can nevertheless be considered a risk factor for the development of mental disorders, with an assumed two- to threefold increased risk for affected children. Notwithstanding the importance of mental disorders, their exclusive consideration is not sufficiently sensitive to the cumulative strains experienced in daily life. Hence, attention to health-related quality of life assesses the subjective view of different everyday functions like emotional well-being, social aspects, and physical activity. It appears that chronic illnesses are associated with a reduced quality of life (Varni et al., 2007). Overall, boys, children with migration background, and those with a lower socioeconomic status more often show negative consequences of chronic (mental and physical) illnesses (Mohler-Kuo and Dey, 2012).

In parents, different sources of strain must be mentioned as well, like the question of causes/possible guilt, worries about the child and financial impairments, but also the additional organizational, temporal, and financial efforts. In treatment, furthermore, they are the main contact for the medical staff as children are not allowed to independently decide on their treatment options. Empirical studies emphasize the strong interdependence of parental and child coping and adaptation reactions (cf Wallander et al., 2009).

Patient education programs – in childhood better called family education programs – have been established to support those coping with chronic illnesses. Their goal is not only to increase adherence to treatment regimes, but also to reduce symptoms and psychological strain. Here, children (and their parents) learn how to handle their disease autonomously. Especially children should – according to their age – be actively integrated into treatment (participative approach). Programs incorporate knowledge about the disease and therapeutic skills, but also about building emotional and social competences to deal with the disease. It has been demonstrated in various studies that the integration of psychological methods into the treatment of chronic illnesses is a very promising approach with medium to large effect sizes, depending on the disease (Graves et al., 2009; Kirk et al., 2011). Once again, the involvement of parents seems to be important. In obesity treatment for children up to 12 years, behavioral approaches that include the parents are more promising than those that do not. Relevant aspects in working with parents in the context of weight reduction programs prove to be self-management strategies (e.g., self-monitoring, self-instruction, goal setting) but also the identification of barriers to the implementation of new behaviors at home, the transfer of knowledge about gratification strategies, and the practice of new behaviors. Especially with younger children, first results suggest that parental trainings alone are even more successful than combined parent–child trainings (Warschburger, 2011).

Conclusion

In many basic research fields of Psychology, developmental approaches have been established. These findings should be better integrated into Health Psychology. So far, a development-oriented perspective has not been realized/implemented in Health Psychology. However, Child Health Psychology can be considered an emerging field within the scope of Health Psychology. Childhood is an important stage in life for the establishment of health-relevant behaviors and, hence, for prevention and intervention programs. These programs have to be tailored to the specific characteristics of childhood to unfold their full potential. This contribution discusses the challenges of a development-oriented approach.

Health-Related Support and Self-help Mutual Aid Groups

Abstract

Face-to-face self-help and support groups provide opportunities to meet and interact with individuals who share a common affliction, disorder, life circumstance, noxious habit, or other adversity, and represent a highly specialized personal community that can mitigate feelings of loneliness, stigma, and stress. The past two decades have seen a dramatic increase in the number of online arrangements for the exchange of support and information about health issues, including chat rooms, bulletin boards, forums, newsletters, and groups on the Internet. This article spotlights recent research on the processes, outcomes, and limitations of these peer support systems.

In the 15 or so years since the original article to this encyclopedia was written, the pace of research on health-related support and self-help groups has quickened. This is largely attributable to the proliferation of online groups, a topic that received only a single paragraph at the end of the original article. Recent years have seen countless people turn to their computers to meet other arthritis sufferers, stroke and heart attack victims, substance abusers, and people with such mental health problems as anxiety and eating disorders (Finn and Steele, 2010). MDjunction.com lists 102 online support groups (OSGs) for mental health topics, including highly specialized groups, like those for people interested in bipolar disorders; there are online venues for teenagers affected by that disorder, for those with alcoholism and anxiety, parents of children with the disorder, pregnant ladies, and those dealing with PTSD concurrently.

Of course, the same medium has been exploited for more nefarious and disturbing purposes, such as sites that promote suicide (Golant et al., 2003), exploit people recovering from sexual offenses (Kernsmith and Kernsmith, 2008), and those that encourage eating disorders (pro-ana and pro-mia). For example, the latter sites depict eating disorders as desirable, describe crash dieting techniques and recipes, coach users on using socially acceptable pretexts for refusing food, such as veganism, hold weight loss competitions, advise on how to best induce vomiting and use laxatives and emetics, and share tips on hiding weight loss from parents and doctors (http://en.wikipedia.org/wiki/Pro-ana). It would not be overreaching to declare that, functionally, these sites offer a support group or network to their devotees. Moreover, the many names that are used to market social support on the Web make it hard to know whether to trust the information and advice offered, much less whether the support being offered has been vetted by any authority who knows the difference between fact and myth and prosocial vs antisocial messages. Hence, as discussed later, there is an urgent need for some form of certification of Websites or quality standards to help consumers seeking support to distinguish between legitimately moderated sites and self-styled 'fly by site' URLs.

Online Support Groups

A recent national US survey of more than 3000 individuals conducted by the prestigious Pew Research Center's Internet and American Life Project (2011) testifies to the growing use of the Internet for peer information and support related to health matters. Although the survey did not inquire specifically about participation in groups, the findings illuminate the kinds of resources sought from peers online and the unique attractions of this medium. They reveal that peers are sought mainly for emotional support, tips on coping and how to communicate with health care professionals, and when a speedy solution for an everyday health issue is needed. The survey also spotlighted the very high use of the Internet among those with rare conditions and chronic disorders (Murray et al., 2005). For example, of those consulting the Internet for a chronic health disease, almost one-fourth were people living with high blood pressure, diabetes, heart conditions, lung conditions, cancer, or another chronic ailment. An even greater proportion of online users with a rare condition accessed peers for advice, counsel, and support; they simply had to reach beyond their existing social ties and even their associates' ties to find people in the same boat or shipwreck. Readers seeking the most comprehensive listings of OSG studies are referred to a chapter by Finn and Steele (2010) and an excellent online bibliography by Azy Barak (http://construct.haifa.ac.il/~azy/refsupp.htm).

The proliferation of Internet social resources for physical and mental health disabilities and concerns has also resulted in the founding of new journals, making it easier for researchers to learn how to conduct methodologically and ethically sound Internet intervention studies. As one example, the *Journal of Medical Internet Research* has published a systematic review of OSGs for depression, noting that this psychiatric disorder is common among people with serious, life-threatening, and chronic diseases, not just people experiencing psychosocial stressors (Griffiths et al., 2009). As most literature reviews observe methodological weaknesses, such as the absence of a control or comparison group and failure to control for cointerventions in a multicomponent program, precluded any firm conclusions about the effectiveness of the group support. Even the strongest conclusion drawn on the basis of the 31 reports (whose characteristics and outcomes are displayed in two tables) was couched in highly tentative language: "Overall, studies of breast cancer ISGs were more likely to report a reduction in depressive symptoms than studies of other ISG types (Fisher $P = 0.02$), but it is possible that this finding was due to confounding design factors rather than the nature of the ISG" (p. e30).

More troublesome, however, is the inclusion of diverse structures and formats of group support in the review. Specifically, it includes such diverse online arrangements as a 12-week structured 'newsgroup' for women with breast cancer, moderated by a psychologist (Winzelberg et al., 2003), a 16-week 'chatroom' for women with breast cancer that was hosted by a professional and also offered continuous access to a bulletin board but lacked a control group (Lieberman et al., 2003), a strictly dyadic intervention involving 4–8 weeks of online chat sessions with the same anonymous partner (Shaw and Gant, 2002), and participation in public listservs/bulletin boards for at least a 12-month period (Houston and Allison, 2002). Still other Internet support group (ISG) formats were mailing list/newsgroups, instant messaging, and other combinations of Internet social contacts. Clearly, such polymorphous entities as those included in this review underscore the need for a common nomenclature for the diverse 'online communities' that marshal, augment, or specialize social support. Although there are ISGs that mimic face-to-face groups, such as the ISG implemented by Winzelberg et al. (2003) that is presented later, there is great variety in online groups and communities, with few guideposts for novice consumers.

More generally, there is a need for clearer standards or guidelines for conducting and reporting Internet intervention research. Several recent documents have aimed to provide such quality control (Rippen and Risk, 2000; Risk and Dzenowagis, 2001). One sterling example is Proudfoot et al.'s (2011) contribution that begins with a 'mapping sentence' that lays out the domain of inquiry and then sets out the 'facets' of the topic being mapped as well as their 'elements,' and a guideline arising from each facet. The sentence employed for online intervention research is somewhat tortuous but inclusive: "An Internet-based intervention is a self-guided or human-assisted program for health promotion, disease and emotional distress prevention, risk factor management, treatment, or relapse prevention that is executed by means of a prescriptive online intervention and/or communication operated through the Internet and used by consumers and patients seeking health- and mental health-related assistance" (p. 86). Examples of the 12 facets produced from this sentence include the target population, the model of change, the type and dose of the intervention, and the program interactivity and degree of synchronicity. An example of a guideline for the latter facet is: "The synchronicity of support and feedback are clearly reported within the program as well as the duration between program sessions, where relevant" (p. 90). These and other guidelines yet to be written for best practices in online intervention research await the views and potential endorsement of individual investigators and professional associations.

Eysenbach et al. (2004) also conducted a review of peer-to-peer online support initiatives, defining their object of study more clearly than the preceding review but nevertheless leaving much ambiguity about the phenomena of interest. They state that they searched for interventions involving "a virtual community (or had a virtual community component), defined for the purpose of this study as a group of individuals with similar or common health related interests and predominantly non-professional backgrounds (patients, healthy consumers, or informal caregivers) who interact and communicate publicly through a computer communication network such as the internet, or through any other computer based tool (including non-text based systems such as voice bulletin board systems), allowing social networks to build over a distance" (p. 1166). Of the 45 publications that met their inclusion criteria, they report that only 6 exclusively involved moderated peer-to-peer interaction over time, the rest being multicomponent interventions. The findings for the six 'pure' ISGs are virtually identical to the review by Griffiths et al. (2009), namely that shortcomings in the study designs, small numbers of participants, and lack of information about the clinical significance of small group differences render the evidence inconclusive. Happily, the review found none of the ill-effects reported for ISGs elsewhere (Houghton et al., 2001; Kelly et al., 2002).

Granted that there is much definitional slippage surrounding the use of the interchangeable ISG and OSG labels, there are nonetheless a few examples of tightly designed Internet studies that bear a strong similarity to face-to-face support groups, except that interaction is not synchronous. One example is Winzelberg et al.'s (2003) study of three 12-week, structured and professionally moderated ISGs composed of 72 women with primary breast cancer. Like a typical face-to-face support group, a mental health professional introduces different topics each week, calling on the participants to share their thoughts and swap their experiences, with time set aside for each group member to 'check in' whenever she logged on, to share a personal profile of herself, and to maintain a private diary of her own reflections. Members of this ISG called Bosom Buddies could also see when their 'buddies' logged on, and were encouraged by the facilitator to exchange support and stay on topic. The findings proved gratifying; at posttest, the effect of the immediate ISGs was to significantly reduce participants' scores on the Center for Epidemiological Studies Depression scale, and to lower levels of perceived stress, and cancer-related trauma, with all effect sizes in the moderate range. Equally important, despite their inability to see and communicate in real time with their 'buddies,' the participants formed close relationships with one another that involved sharing family events and ceremonial occasions (e.g., birthdays and anniversaries), and even expressed concern when they had not heard from a member for longer than usual. Some participants developed off-line relationships, presumably integrating their buddies into their natural social network, thereby further sustaining their mutual access to support. Perhaps future ISGs could aspire to such beneficial social side effects when the participants are geographically proximal enough to affiliate with one another.

Yet questions arise about the external validity of this particular ISG and about the filtering that occurred at the time of study intake. On the latter score, we learn that, of the 151 women who replied to the advertisement for the ISG, 79 did not enroll, of whom 39 or approximately 50% decided not to participate once they were told the details of the study. Access to computers was not an issue because they were provided to those who needed one. So the question is why so many did not enroll, and the answers would be instructive for future trials of ISGs. Was it fear of the unknown or perhaps fear that the group would raise subjects that the women preferred not to consider, or that it would attract members who pose new threats by virtue of their worse prognoses or superior coping behaviors? As it turns out, those who did enroll were a highly educated

sample; 64% had at least a baccalaureate degree and another 28% had attended some college. In future reports of these initiatives, it would be highly informative if the investigators were to collect information about the characteristics of those who decline participation and solicit their reasons for opting out. Given the flexibility of asynchronous ISGs that allow users to go online whenever it is convenient or when the need for contact with others arises, time constraints are not as likely to be cited as an obstacle to group participation as they are for scheduled, face-to-face group meetings.

More generally, questions are being raised about the reach and representativeness of people who participate in online support programs and other types of computer-mediated public health programs, leading Bennett and Glasgow (2009) to recommend targeting high-risk groups such as older adults, people in rural areas, and people with chronic conditions that require careful self-surveillance. In addition, by way of standard setting, they recommend that Internet interventionists report the size of the target population, the size of those who were invited to participate, the proportion who are eligible, and of those, the proportion who participate, and finally, how representative the final sample is. To this must be added the attrition rate because there is growing evidence that a significant proportion of those who enter online trials lose interest and quit (Eysenbach, 2005).

Another relatively recent development in the evaluation of online support is the inclusion of measures that assess consumers' psychological sense of control over their own health care, health-related decision making, and ultimately their own health status. Investigation of the empowering effects of self-administered programs has yielded insights into the virtues of being accepted and validated by peers, being useful to others, gaining benefit from the very process of writing about one's experience and processing the accompanying effect, and reducing self-stigma by virtually meeting people from diverse cultures and geographic locations who share and have overcome similar plights (Barak et al., 2010). A fascinating report of both empowering and disempowering processes that unfold in OSGs not only substantiates the preceding empowering processes, but also documents the perceived outcomes reported in interviews with ISG participants (van Uden-Kraan et al., 2008). Specifically, after contacting the Webmasters of Dutch ISGs to ask them if the members could be informed of a study about their ISG experience, 32 participants in groups for people with breast cancer, fibromyalgia, or arthritis consented and were interviewed. Based on a thematic analysis, the outcomes they collectively attributed to their group experience include: "being better informed; feeling confident in the relationship with their physician, their treatment, and their social environment; improved acceptance of the disease; increased optimism and control; enhanced self-esteem and social well-being; and collective action" (p. 405). Moreover, a study of empowerment among people living with HIV/AIDS employed structural equation modeling to examine the downstream effects of empowerment processes involving the receipt and provision of informational and emotional support, along with the positive meaning gleaned from the group experience (Moa and Coulson, 2012). The findings show that these processes selectively lead to both a higher level of self-care self-efficacy (confidence in one's ability to look after one's own health) and more adaptive coping, which lead in turn to higher life quality.

A final observation about online support resources is that their sheer abundance and variety make it very difficult to distinguish professionally moderated groups from mutual aid self-help (MASH) groups. Indeed, as the authors of this encyclopedia article, we were often challenged by insufficient detail about the format, leadership, eligibility criteria, and duration of the online groups and communities that were the subject of study to classify them as support groups or self-help groups. And if we could not tease the two apart, imagine the quandary facing the naïve Internet user who is searching for a supportive personal community. It follows that, in the future, it will be necessary to provide greater detail and clearer definitions of these online resources, with sites hosted by spokespersons who can answer questions about what each site does and does not offer and how it goes about providing support.

MASH Groups

The principal distinction that is made when support groups and self-help groups are compared is that the latter do not employ professional facilitators, do not limit the length of participation, and generally rely on mutual aid and a structured program of activities or steps to help their members. In Borkman's (1976) terms, self-help groups draw on their members' experiential knowledge, not expert information or training. Recent developments in research on self-help groups are reviewed below, beginning with selected studies of take-up and attrition, followed by investigations of the process and outcomes of MASH groups.

Attraction and Attrition

Few studies have investigated attrition and retention factors within the context of self-help groups. Although self-help groups have an indefinite potential duration, not all groups survive over the course of months and years. Given the potential benefits of self-help groups, it is important to identify the factors that attract members and those that influence attrition. Randomly selecting self-help groups addressing a variety of concerns (except for anonymous groups such as Alcoholics Anonymous) from the registration database of the Self-Help Network of Kansas, Wituk et al. (2002) identified characteristics that distinguished between active and disbanded groups. When compared to groups that had disbanded, active groups had a significantly higher number of new members within the past year, a significantly higher average meeting attendance, had been in existence for a significantly longer period of time, had a greater number of people participating in leadership roles in groups, had membership recruitment and maintenance techniques, and received funding from local agencies.

If a higher number of new members within the past year contributes to the survival of self-help groups, recruitment should concentrate on people who match the characteristics of those who join self-help groups. What limited research on this topic exists reveals some of the social and psychological characteristics of cancer patients who choose to join online

self-help groups (Hobye et al., 2010). Individuals taking part in a cancer rehabilitation course were invited to participate in an online self-help group. Those who chose to participate in the online self-help group were generally younger, with a higher socioeconomic status, and married or cohabitating. There were no significant gender differences, and users and nonusers did not differ significantly on measures of psychological well-being and quality of life. Of special interest, cognitive avoidance as a coping style also discriminated between users and nonusers, with nonusers endorsing the use of cognitive avoidance significantly more often. This suggests that cancer patients who tend to employ forms of coping that reflect disengagement from stressors are unlikely to both join and benefit from groups that involve disclosure of threatening feelings and thoughts. However, as this was a study of an Internet self-help group, it is not yet determined whether these distinguishing characteristics are generalizable to face-to-face self-help groups.

Double Trouble in Recovery (DTR) groups are dual-focus 12-step self-help groups for those with substance addiction and a comorbid mental health disorder. They have been the subject of much evaluation, including a study of predictors of retention of members recruited from 24 DTR meetings over a 1-year period (Laudet et al., 2004). Significant predictors included: "older age, greater number of lifetime arrests, abstinence from drugs and alcohol in the preceding year, not taking psychiatric medication, more psychiatric symptoms during the pre-baseline year, being more troubled by substance abuse than by mental health, greater level of self-efficacy for recovery, residing in supported housing and being enrolled in outpatient recovery at follow-up" (p. 290). These results, portraying a more mature, motivated, and service-linked profile, are likely specific to these unique dual-focus groups.

Process

Though few studies have delved into the processes and mechanisms through which MASH groups exert an impact on health outcomes, some authors have attempted to identify the mediators. In their investigation of the DTR groups, Magura et al. (2003) found that the degree of involvement in DTR groups and their sponsoring organization (frequency of attendance, sharing at meetings, chairing meetings, speaking with other group members about issues) was significantly positively associated with drug and alcohol abstinence and associated health maintenance behaviors (medication adherence, keeping doctor's appointments, self-care). Furthermore, higher internal locus of control and degree of participant sociability mediated the relationship between DTR involvement and abstinence. Taking into account the relationship between DTR involvement and health maintenance behavior, internal locus of control, sociability, installation of hope, and spirituality all mediated the relationship. These findings are not surprising given that internal locus of control increases individuals' self-efficacy for recovery and sociability facilitates the formation of meaningful relationships and mutual aid in the recovery process (Magura et al., 2003).

The formation of close social ties in self-help groups has also been found to promote member retention and benefit. Drawing on a sample of military veterans who participated in MASH groups for drug and alcohol addiction, Humphreys et al. (1999) found that enhanced friendship networks at 1 year follow-up partially mediated the relationship between group participation and abstinence. It stands to reason that increased extragroup affiliation with other group members who also endorse abstinence is implicated. Even the formation of one good friendship with a group member can spur continued group attendance (Kelly and Moos, 2003). In a separate study of a DTR group, by the first year follow-up, Laudet et al. (2004) found that longer attendance predicted drug and alcohol abstinence, and this relationship was partially mediated by higher levels of social support, presumably based on the development of friendships. In the addictions field, it seems that group programs like these supplement or supplant the negative influence of associates with network members who promote a healthier way of life.

In a fascinating study of 'Clubhouse Communities' for people with mental illness, Pernice-Duca and Onaga (2009) report similar findings about the value of supportive peer ties for people affected by mental illness. Clubhouse programs are much like psychosocial rehabilitation centers, offering support mainly from peers and egalitarian relationship with a small cadre of staff. The 'members' engage in 'work-ordered day units' that require interdependence among the unit members, giving them reciprocal and meaningful social roles, which reflect a recovery model of rehabilitation. Selecting 221 members of 15 clubhouses, the researchers conducted two interviews with each member, separated by an interval of 12–15 months. They measured the number of hours and work-ordered units members participated in, along with several network structural properties (e.g., size) and support-related variables (e.g., perceived support), examining their relative and combined strength in predicting a validated measure of recovery. The findings at both the first and second interviews revealed that, after inserting appropriate statistical controls (e.g., baseline level of functioning), three support network variables made significant and relatively large contributions to the members' recovery: the size of the network, the extent of support, and reciprocity.

Given that more intensive group affiliation has been implicated in positive outcomes for 12-step group members, it should be an area of focus for intervention research. Intensive referrals (those referrals in which a counselor contacts a current self-help group member to accompany a new client to a meeting) have resulted in more frequent attendance, group engagement, and longer periods of abstinence for group attendees compared to clients who received standard referrals among veterans with substance use disorders (Timko and DeBenedetti, 2007). In short, in addition to referring people to 12-step programs, health care professionals should link them to other group members they can befriend and integrate in their natural social network. Clearly, one important limitation of online self-help groups attended by people who are at a geographic distance from one another is the barrier to their formation of a face-to-face friendship in the larger personal communities they inhabit.

Outcomes

With respect to the impact of MASH groups on participants, research continues to focus mainly on 12-step self-help groups,

with the main focus on the participants' psychological functioning. In a study comparing drug and alcohol abstinence among low-income veterans who attended a 12-step self-help program and those given cognitive behavioral therapy, Humphreys and Moos (2007) found comparable short-term psychiatric improvement, but the 12-step program yielded significantly higher abstinence rates at the 2-year follow-up. Pistrang et al. (2008) provide an excellent review of the effects of 12-step self-help groups for individuals with three types of mental health problems, namely chronic mental illness, depression/anxiety, and bereavement. Focusing only on methodologically strong studies containing quantitative evaluations that allowed for some degree of causal inference about the effectiveness of self-help groups, Pistrang et al. (2008) conclude that seven of the studies show positive and significant improvement, including two randomized controlled trials (RCTs). The other five did not result in any changes, and none of the evaluations reported adverse effects. Outcomes included use of and adherence to psychiatric medication and a variety of standardized self-report measures of psychiatric symptomatology. In this regard, the authors suggest that future studies should consider other relevant outcomes that assess life quality, such as reduced isolation, increased confidence, changes in self-identity, and a sense of empowerment.

Promising results have also been reported from other RCTs of self-help groups. In an evaluation of a self-help group for Chinese people with a family member affected by schizophrenia, Chien et al. (2008) reported that participants experienced a significant decrease in caregiver burden, an improvement in family functioning, and an increase in support received compared to those in the wait-listed control group. In addition, the length of hospitalization of the family member with schizophrenia was reduced compared to those in the control group. Regrettably, because this group did not adhere to a clearly defined treatment protocol amenable to replication, its generalizability to other samples of caregivers is unknown. To optimize the potential for knowledge transfer, self-help initiatives such as this one need to be manualized and implemented in ways that are faithful to the blueprint.

More than any other illness, depression has commanded the attention of self-help group evaluators. In a recent meta-analysis of the effects of 'peer support groups' on recovery from depression, Pfeiffer et al. (2011) included nine rigorously designed RCTs that compared the effectiveness of peer support groups vs treatment as usual (TAU), and in a separate meta-analysis, compared the effectiveness of peer support groups vs cognitive behavior therapy. They found a significantly greater reduction in depressive symptomatology and treatment cost among participants in peer support groups compared to TAU, but no significant differences between those support groups and those receiving group cognitive behavioral therapy. However, it is not clear whether the peer support groups were strictly self-help groups or whether they were professionally led support groups; the authors state that "Peer support groups could be professionally led; however, in order to distinguish these from group psychotherapy (i.e., cognitive behavioral therapy), group interventions needed to either be described as peer support (or mutual support or self-help) or to be organized so that participants determined the majority of the topics and content of discussion" (p. 30). Regardless of their significantly lower cost, without knowing exactly how professionals function in these groups, and how active they are, it is impossible to credit peer support for an impact on depression equivalent to professionally administered cognitive behavior therapy.

Conclusion

OSGs are a welcome addition to the armamentarium of supportive resources available to the public. For people who are loathe to approach a professional practitioner directly or attend a self-help or support group meeting, and for people who live in remote areas or whose state of health precludes attendance at face-to-face meetings, online resources can be a boon. However, at this early stage in the evolution of these online support arrangements there is an urgent need for greater Internet literacy so that they can identify legitimate and credible resources and distinguish among the many modes of communication available to them. Quality standards are being developed, both to protect users from sites of dubious quality and intent, and to guide the increasing number of individuals and organizations that want to design ethically sound and user-friendly Web-based supportive resources. Although the Internet's interactive technology has brought about a monumental change in what we can communicate and with whom, it will only fulfill its democratizing and empowering vision when people of all ages, ethnicities, and income levels contribute, thereby fostering greater social integration and mutual aid.

Abstract

In qualitative health research qualitative social research methods are applied to study problems at the interface of health or illness and social life. Qualitative research is an umbrella term of research characterized by openness, subjectivity, process orientation, and interpretation of meaning. Interviews, group discussions, observations, and document analysis are the main modes of enquiry. Critiques of qualitative health research that is predominantly related to issues of sample size and generalizability ignore central concepts of qualitative methodology. Qualitative health research has been discussed within the premises of an evidence-based medicine. It has made valuable contributions to the field of health research.

Qualitative health research refers to the broad area of health research applying predominantly qualitative social research methods to study problems at the interface of health or illness and related social issues such as health care. Qualitative research is an umbrella term for a wide spectrum of different social research methods and methodologies. The term implies a clear distinction from 'quantitative' research – a *term* that is not prominent in the health sciences, although health sciences are dominated by quantitative research methods. Rather, distinctions are made with regard to the perspective of enquiry, for example, public health, epidemiology, clinical research; the domain of research, for example, oncology, rheumatology; the health strategy applied, for example, prevention, or rehabilitation; or the developmental phase of an intervention, for example, from basic research via translational research via clinical research to health services research. Qualitative health research comes into play, the more important social aspects of health, illness, and care become – that is, people and their behaviors, decisions, preconceptions, attitudes, interactions as well as social groups including institutions, systems, rules, structures. Qualitative health research is especially suited to deal with aspects of health interventions and health care, as well as social conditions or consequences of illness.

Like 'quantitative' research, qualitative research comprises a plethora of different ideas, approaches, methods, methodologies, and concepts. Different qualitative approaches even resort to different epistemologies. However, there are some core characteristics of qualitative research that make it particular, especially when they result in quality criteria that contradict health researchers' thinking that has been trained in biomedical research traditions.

Characteristics of Qualitative Research

Qualitative health research draws from traditions from different fields of research, including the social sciences/sociology, ethnology, psychology, and linguistics. Common to all qualitative approaches is a focus on persons or people within social relations. The spectrum of different methodological approaches ranges from the description, reconstruction, and analysis of subjective perspectives, attitudes, behaviors, and social interactions, including the reconstruction of structures in social fields, and the interpretation of basic or latent meanings of actions (Meyer and Flick, 2010).

Openness is a core characteristic of qualitative research with very different facets. In terms of research designs, qualitative research is set up to allow what is unknown or unexpected to emerge during the conduct of the study. It also means that researchers are able to adopt their design or methods during the course of a study, if there are good reasons to do so and could not be anticipated at the outset of the study. Qualitative researcher might need to adopt the research question if it turned out to be flawed, to be imprecise, or to make too restrictive assumptions. The sampling criteria of participants might change or develop during the course of the study (e.g., theoretical sampling in grounded theory; Glaser and Strauss, 1967). Methods of collecting data should be set up to allow for openness, for example, interview questions that stimulate interviewees to talk openly and provide rich data. Openness also refers to a specific stance toward research subjects, for example, by providing conditions – a quiet and undisturbed room, a trustful and accepting interviewer, taking care that the participation of the interviewee is indeed voluntary – in which a person is able to talk freely. Openness also refers to the data format, that is, in contrast to fixed or closed response formats. Usually data in qualitative enquiries are synonymous to texts that need further interpretation. Openness can also refer to an important characteristic during analysis, where it is important to be open to very different interpretations of data to provide a deeper and more comprehensive understanding of the phenomenon under study.

Subjectivity is another core characteristic of qualitative research. Often qualitative research aims to reconstruct the (spectrum of) subjective perspectives and attitudes of different people, for example, patients, professionals, or other stakeholders, both with regard to individual persons and in social situations. Also, the researcher as a subject is acknowledged as part of the research process. Researchers' interests, motivations, expectations, values, personal experiences, theoretical stances, and knowledge are known to influence every step of the research process. Instead of pursuing the impossible task of

making the researcher invisible or 'objective,' researchers have to be very aware of how their characteristics influence the research process and to take this into account during the different phases of a project. In other words, the subjectivity of the researcher is acknowledged and harnessed. Subjectivity also relates to an epistemological idea that research does not result in objectively valid findings, but rather in subjective 'readings' of a social phenomenon. That means, qualitative research does not strive to discover the one and only objective truth, but to provide statements that are well founded in the data and developed with methodological rigor.

Process and iteration: A linear research process is seen as an ideal in biomedical research traditions. In qualitative research, research processes are rather circular and iterative. For example, data acquisition, analysis, and theoretical interpretation are not different research phases but can be deeply interrelated. In a qualitative interview, analysis should start as soon (or late) as the interviewee responds to the first question. In grounded theory, analysis and theoretical considerations form the basis of further sampling. Text is not read and coded once, but it is reread and revisited repeatedly. This procedure stimulates different interpretations and allows to develop categories and theoretical assumptions that are consistent with the data. The term *process* also refers to the fit of qualitative research method with the object (or subject!) of research, which requires recurrent reflection. Orientation toward processes also means that inductive reasoning has an important part in the research process. Principles of induction are used to develop new theories grounded in the data without ignoring the value of deductive or possible pitfalls of inductive reasoning. Distant from the domains of qualitative research, the dominance of hypothetico-deductive reasoning in scientific epistemology runs the risk of neglecting the process of hypothesis development. Qualitative research offers well-founded approaches for the development of hypotheses or theories. Process orientation, together with openness and subjectivity, points to another characteristic of qualitative research, that is, the need for transparency in terms of rigor in documenting and disclosing methodological decisions made during the course of a study.

Interpretation of meanings is also at the core of qualitative research. Doing qualitative research is doing interpretation work. While it could be argued that interpretation of meaning is a general task of research, qualitative research is particular in this regard because here interpretation is an integral part of the analysis (and even research) process. It is not confined to the final discussion phase of study results (Meyer et al., 2012).

Methods of Qualitative Inquiry

Interviews

In health research a prominent method of inquiry is doing interviews (Pope and Mays, 2009; Karbach et al., 2012). Interviews are characterized by a direct, personal interaction of an interviewer and an interviewee. It is also possible to have more than one interviewer. Also, it is not uncommon to have more than one interviewee present, for example, family members or caregivers in phases of special care needs. Usually, interviews are conducted by a face-to-face interaction, although other modes are also practiced, for example, telephone interviewing or use of interactive media. Very different interview forms exist depending on the purpose of the interviews. For example, Kvale (2007) distinguishes conceptual interviews, narrative interviews, and discursive interviews. He also refers to factual interviews and confrontational interviews, which can be thought of as rather active interview forms that do not always comply with the core characteristics of qualitative research introduced above, for example, the characteristics of openness, orientation toward the subject, or the need for interpretation. Also, there are special subject groups who require special forms of interview, for example, palliative care patients, children, persons with different levels of language competence as in certain immigrant groups, elites/professionals, and persons with intellectual disabilities. Interviews differ according to the extent of standardization or reduced openness in the conduct of the interview. On the one side there are standardized interviews that have fixed questions to be asked in a defined order. On the other side there are narrative interviews or informal conversational interviews, which provide the interviewee with an incentive to talk about a certain topic, without making further restrictions. The more open the type of interview, the more important is the task of the interviewer to ensure the flow of communication. One part of the analysis is then to give explanations why the interviewee has chosen the contributions presented in the interview. Between structured and narrative interviews the popular form of semistructured interview (also called the interview guide approach (Patton, 2002)) can be located. Here, an interview guide is developed containing the important topics the interview should cover, some pivotal questions, and possible further questions. In this type of interview it is important that the interviewee is stimulated to talk about each of the topics deemed important, without necessarily adhering to the specific wordings of the questions or their order. Choice of the extent of standardization in interviews should depend on the knowledge of researchers in the field of interest.

Group Discussions/Focus Groups

Group discussions or focus groups are sometimes referred to as a special form of interviews (Kvale, 2007; Patton, 2002). Focus groups have found their way to health research via marketing research, where it has long been a prominent tool (Krueger and Casey, 2009). Present use of focus groups in health research seems to primarily resort to this pragmatic approach. However, there have been traditions in other fields and countries that have provided, besides others, substantial methodological advancements, for example, Morley (1980) within the framework of cultural studies in the United Kingdom, or the work of the Frankfurt Institute for Social Research in Germany shaped by the early work of Pollock (1955) and its successors, including the documentary method developed by Bohnsack (2010).

Besides similarities between individual interviews and group approaches, it should be acknowledged that group discussions share potentials that make them qualitatively distinct from individual interviews. Most importantly, interactions among participants can be used as an additional resource in interpretations. They render focus groups/group discussions especially suitable for gathering opinions at the

group level, because participants tend to check and balance each other. Also, there are sensitive topics, for example, relating to stigmatization of persons, that are more easily conveyed in group settings with persons deemed as similar to oneself than in individual interviews. A discussion of limitations of focus groups can be found in Patton (2002).

Observations

Observations, especially field observations, represent a pivotal method of qualitative inquiry. However, it is underrepresented in current qualitative health research (Pope and Mays, 2009; Karbach et al., 2012). Scientific observations are different from everyday life observations in that they serve a certain purpose, are planned and documented systematically, and are scrutinized with regard to their methodological rigor. There are different forms of observations: they can be open or covert, that is, persons either knowing or ignoring that they are observed, or knowing or ignoring the reasons for being observed. However, covert observations are highly sensitive to ethical considerations and not compatible with the openness characteristic of qualitative enquiry. The degrees of participation of the researcher may vary. For example, researchers can become part of the setting, both in terms of a patient and professional. The study by Rosenhan (1973), in which persons were admitted to psychiatric wards after having presented some fake symptoms and behaving as normal as possible afterward, is a famous example of the use of participant observation. Alternatively, researchers participate by 'shadowing' persons in their daily activities, that is, they closely follow a person over an extended period of time (McDonald, 2005). In medical anthropology, participant observation has been successful, for example, in improving our understanding of the effects of public needle exchange programs in drug users to prevent HIV infection programs which turned out to be positively related in epidemiological studies (cf Bourgois and Bruneau, 2000). Nonparticipatory observations can be found, for example, in studies using video recordings of patient–physician interactions (cf Themessl-Huber et al., 2008). Observations can be made either in the field, that is, where the phenomenon of interest occurs, or in the laboratory. While the latter can be used to control for possible biases, the former has the advantage of being a representation of people's lived experiences. The psychological tradition of self-observation (introspection) is hardly applied in qualitative health research today. Observations are often combined with other modes of inquiry, as had been done by a famous sociological work related to the analysis of the consequences of unemployment, the 'Marienthal' study by Jahoda and coworkers in the early 1930s in Austria (Jahoda et al., 1971). In this study, participatory research had been combined with very different research methods, including nonreactive techniques such as documentary analysis, analysis of official statistics, or elements of action research, surveys, and tests.

Documents

Retrieval of documents can be viewed as a nonreactive method of inquiry. Its primary advantage is that these documents have not been set up with the knowledge of being analyzed in a research project. This reduces an important social desirability effect in qualitative research. However, researchers have to be aware of other social processes pertinent to the production of the document. For example, filling in a medical record should be related to the purpose of the documentation and is based on specific social codes. Another example are minutes of a meeting that may be used to analyze different social roles of the participants. Document analysis, therefore, has always to take into account the context in which these documents are generated. It is a challenge of document analysis to develop a clear-cut rationale of how these behavioral traces relate to the theoretical construct of interest. Digitalization of social life – especially so in relation to internet activities – offers a renaissance to the analysis of documents within qualitative research (example in Willis et al., 2012).

Methods of Qualitative Analysis

There is a considerable gap between a plethora of available methods of qualitative analysis and the proficiency of qualitative health researchers in doing different types of analysis. Sackett's and Wennberg's dictum of choosing appropriate methods for research questions (Sackett and Wennberg, 1997) – and not vice versa – holds true for qualitative analysis as for any analysis in empirical research. In practice, this knowledge is difficult to obtain because each method of analysis needs to be learned by experience and experienced teacher and colleagues. Also, contrary to statistical analysis, different traditions of analysis have emerged in different regions confined to cultural and language boundaries. Qualitative research requires a high level of language competence and a thorough understanding of the sociocultural context of the study. These challenges might have contributed to a lack of convergence in this field from an international perspective.

The choice of method of analysis is related to the type of phenomenon under study. If a researcher is interested in manifest views of subjects or stakeholders, then a content analysis approach that summarizes what is being said deems appropriate. There is a tradition for this type of analysis, especially in eliciting special patient groups' views, in documenting their experiences with illness and care (cf Greenhalgh and Hurwitz, 1998). These can be single case studies or – relating to groups of patients – descriptive studies (cf the taxonomy of qualitative study evidence by Daly et al., 2007). The starting point of analysis can be a thorough analysis of single cases, and this could result in the development of different types of cases. Another starting point of analysis could focus on categories beyond the single case and could try to develop common themes.

The strength of qualitative analysis is to move beyond the apparent or manifest by elaborating latent characteristics or mechanisms through the researcher's interpretation. From a psychological perspective this relates to all those important aspects of people's lives that are situated beyond their immediate grasp and, thus, have to be inferred from the data. From a sociological perspective social phenomena have to be reconstructed to identify their underlying conditions, such as beliefs, rules, norms, values, structures, power relationships, or societal discourses.

Beyond the manifest–latent distinction and the type of explanations the researcher is targeting at, it is also important to know how far-reaching the aim of a research project is. For example a qualitative health researcher could be interested in a local theory on why people do not respond to regular screening invitations in a national screening program for colorectal cancer (e.g., Hall et al., 2013). In a further step one would try to develop a general theory on reasons for (non) participation in public health programs. Generalizable theories are at the top of the evidence hierarchy in the taxonomy of Daly et al. (2007). The most elaborated methodology to develop such theories is the 'grounded theory approach' introduced by Glaser and Strauss (1967), and further developed by their colleagues and scholars (e.g., Corbin and Strauss, 2007; Charmaz, 2006). Grounded theory integrates both a case perspective and an overarching categorical perspective, especially so by applying the method of constant comparisons. It posits that theoretical statements should be developed from data and that their conceptual assumption should be rigorously checked against the data. The grounded theory approach still represents a landmark in qualitative health research.

Critiques of Qualitative Health Research: Sampling, Sample Size, and Generalizability

Qualitative research has ever since been confronted with the view that sample sizes are too small to secure representativeness and therefore generalizability. Rather, this research is useful in exploring a new field of interest that should be investigated by other research methods later on. The emergence of grounded theory contradicts this assumption. Sample size is still a lively debated issue (Patton, 2002). The specification of a necessary number of subjects should always be related to the aim and scope of the research question. It should be kept in mind that there is a trade-off between the number of subjects that are included in the analysis and the depth or thoroughness by which each subject can be analyzed. A well-founded, targeted sampling of research subjects is at the heart of qualitative inquiry.

Qualitative analysis does not strive toward statistical generalization. However, other models of generalization are relevant to qualitative enquiry, such as analytic generalization and transferability (Polit and Beck, 2010). In analytical generalization, researchers aim to develop their theory by an interplay of inductive and deductive (confirmatory) research processes. An analysis of this kind should be able to represent all relevant aspects of a field of interest. It should be able to capture the diversities, that is, the complete range of phenomena in the field of interest. The idea of data saturation of grounded theory is related to this type of generalization – albeit difficult to argue for in practice. This approach toward generalization has implications for the sampling procedure. For example, one such strategy of sampling, the maximum variation, aims at including extreme or deviant cases, from which a lot can be learned. On the other hand, convenience sampling (i.e., sampling those that can be recruited easily) is the least desirable strategy (Patton, 2002).

Qualitative Health Research in an Era of Evidence-Based Medicine

Evidence-based medicine (ebm) has been defined as "the conscientious, explicit, and judicious use of current best evidence in making decisions about the care of individual patients." (Sackett et al., 1996: p. 71). The ebm approach evolved from a perspective of clinical epidemiology. The use of hierarchies of study designs, the use of critical appraisal of original studies, and the development of systematic reviews have been hallmarks of this movement. It has spread over to other health-related fields such as nursing, physiotherapy, or rehabilitation. Although ebm has been recognized as a threat to qualitative health research (Nelson, 2008), it has moved the field toward new directions and fostered new methodological reflections (cf Morse et al., 2001).

Qualitative studies can have their own place as evidence in clinical decision making. The naturalism of qualitative studies, that is, understanding health-related behavior in its everyday context, has been acknowledged. Or, understanding problems in the implementation of evidence-based medicine into practice is another important domain of qualitative research (Grenn and Britten, 1998). Although the idea of a hierarchy of study designs in answering questions of clinical practice (Daly et al., 2007) has not been widely adopted, the interest in qualitative studies has increased remarkably (Nelson, 2008). However, the appraisal of qualitative studies is still a much debated and contested area (Dixon-Woods et al., 2004). This is exemplified by a number of substantially different approaches, including checklists, explication of general criteria, appraisal within the usage of a specific approach (e.g., discourse analysis), among others. So far, there is no consensus about these issues in the qualitative research community. Quality criteria for qualitative studies (e.g., Cohen and Crabtree, 2008), as well as criteria concerning the reporting of qualitative studies (e.g., Tong et al., 2007), have found a broader audience. However, important issues of evaluating qualitative studies have not been resolved and, consequently, the use of checklists to appraise the quality of qualitative studies has not been thoroughly adopted in the qualitative research community (Barbour, 2001). It is of interest to see that prominent clinical journals, such as the British Medical Journal (e.g., Jones, 1995; Greenhalgh and Taylor, 1997; Mays and Pope, 2000), the Journal of the American Medical Association, or the Lancet (Malterud, 2001), have published contributions on qualitative methods of inquiry (e.g., Giacomini and Cook, 2000), paving the way to subsequent original qualitative studies. Moreover, the need to integrate qualitative studies in systematic reviews has been acknowledged quite some time ago, for example, in the field of health technology assessment by Murphy et al. (1998) and clinical research (Campbell et al., 2003), which in turn brought another impetus into the quality debate (e.g., Barnett-Page and Thomas, 2009). This new proximity of qualitative inquiry to biomedical research is also apparent in a new movement toward so-called mixed method studies (Song et al., 2010), which relates mainly to a pragmatic research tradition (although critically reviewed by some researchers, e.g., Miller and Crabtree, 2005: p. 610).

Contributions of Qualitative Health Research

It is impossible to summarize the contributions of qualitative health research to the field of health research in a single paragraph. Therefore, a few lines of enquiry will be outlined. There are famous and seminal qualitative studies on mental illness. Qualitative research in psychiatry is strongly related to institutionalization and deinstitutionalization of persons with mental illness. For example, a classical work of Erving Goffmann (1961), Asylums, deals with the psychiatric institution as a total institution, a work with wide recognition beyond the field of psychiatry. David Rosenhan (1973) dealt with the question of how the assignment of the 'patient role' contributes to the way of how patients with mental illness are treated within psychiatric institutions. Denise Jodelet (1991) conducted a study on social mechanisms of how mentally healthy and mentally ill people construct their social world in a small French town where formerly hospitalized patients lived within the homes of the villagers. From an anthropological perspective Sue Estroff (1985) investigated the life of persons with chronic mental illness who were discharged to their community. Another example of qualitative enquiry is the work by Ulrike Hoffmann-Richter from Switzerland, who thoroughly analyzed how schizophrenia is covered in print media and what this means for the stigmatization of persons with the diagnosis of schizophrenia (Hoffmann-Richter, 2000). Outstanding contributions to qualitative health research have been made by one of its founding fathers, medical sociologist Anselm Strauss, and his research affiliates. In the academic environment of the University of Chicago, Strauss learned to examine illness from the perspective of the patient. His early work related to the process of dying (together with Barney Glaser; Glaser and Strauss, 1965, 1968), a work that still resonates in the field. Inherent in this work was the concept of illness trajectory which became important later on in research on chronic illness. Together with Juliet Corbin he analyzed the role of family members in the care of chronic patients, as expressed by the concept of *kin work* (Corbin and Strauss, 1988). His methodological work on the development of the grounded theory approach has become seminal to the broad field of qualitative health research (Corbin and Strauss, 2007). An important line of research is related to the integration of the perspective of the ill persons by means of illness narratives (Kleinman, 1988; Greenhalgh and Hurwitz, 1998; Herxheimer et al., 2000) which can provide the basis for further in-depth analysis. Qualitative research methods are also central to feminist health research and medical ethics. Here, qualitative research is instrumental in identifying tacit assumptions like beliefs, values, or societal powers/power relationships. While qualitative health research still appears to be prominent in the Anglo-Saxian and European research literature, threads of qualitative enquiry have also developed in Latin America and in African countries.

Health Risk Appraisal and Optimistic Bias

Abstract

People's beliefs about the hazards they face, their 'risk perceptions,' can affect their actions and emotions. These perceptions are often quite different from risk assessments made by experts. Experts emphasize the numerical probabilities of hazards, a metric that is poorly understood by laypeople. Just as hazards have many dimensions, risk appraisals are influenced by many factors and are subject to a variety of errors and biases. One in particular is the optimistic bias (unrealistic optimism), a tendency to believe that our own vulnerability to hazards is less than that of our peers.

One reason for expert–layperson disagreements is the public's difficulty in understanding numerical presentations of probabilities and odds. For example, people tend to overweight the representativeness of single cases and small samples (Tversky and Kahneman, 1974), and exaggerate the probability of rare events (Slovic, 1987). Another reason is an optimistic bias (or unrealistic optimism) about personal risk, a tendency to believe that one's own vulnerability is less than that of one's peers. Depending on the context, underestimation of risk may be harmful or beneficial.

A third reason for disagreement is that people's judgments of risk often depend on their emotions, which can either facilitate or hinder their understanding of risk information (Loewenstein et al., 2001).

Importance of Health Risk Perceptions

Perceptions of health risks can influence the actions people take to prevent illness and injury, the decisions they make to seek medical care, their choices among treatment options, and their adherence to treatment requirements. Recent work shows that this may be particularly true for affective and intuitive perceptions of risk (i.e., feeling at risk) rather than deliberative perceptions of risk (e.g., ratings on a percentage likelihood scale) (Weinstein et al., 2007). Public controversies over the risks created by government and corporate action are common. During these controversies, scientists and members of the public passionately disagree, demonstrating that laypeople do not passively accept the risk judgments of experts.

The controversy and complexity of risk appraisals suggest that it is important to understand how these appraisals are formed, how accurate they are, and how they influence decisions and behavior. Furthermore, as research continues to identify new risks and 'risk factors' (attributes of individuals or environments that alter a person's likelihood of harm), the need grows to explain this information clearly so that individuals can make better decisions about their health. Such education about risk is the goal of the specialty called 'risk communication.'

Defining 'Risk' and 'Risk Perceptions'

Before pursuing this topic it should be mentioned that the term 'risk' has several meanings. Sometimes 'risk' is used synonymously with the word 'hazard,' denoting a specific undesirable outcome. In this sense, cancer, the common cold, and automobile accidents are all 'risks.' 'Risk' is also used as a synonym for 'probability,' referring to the probability (or likelihood) of the undesirable outcome. Thus, one can speak of the risk that a person will develop cancer. 'Risk' is frequently used in still another way, as a synonym for 'danger' or 'threat' (for example, 'How risky is smoking?'). The term 'risk perceptions,' then, is a general term that refers to the various beliefs that people hold about health and safety hazards.

How Do People Think about Risk?

Dimensions of Hazards

Hazards have many dimensions. According to classical theories of decision-making, the key attributes of a hazard are the probability that it will occur and the severity of the undesirable consequences should it occur.

Pioneering research by Lichtenstein et al. (1978) demonstrated that laypeople are also influenced by hazard attributes that are not so obviously important. When scientists are asked about the riskiness of different illnesses and technologies, their judgments strongly reflect the number of people who die annually from each one, thus reflecting both seriousness (deaths) and likelihood (number of events in a particular population). Lay judgments, however, are only moderately related to the number of fatalities. In addition, laypeople respond to whether the risk is familiar or unfamiliar, manufactured or natural, voluntary or involuntary, and other factors. Summarizing the many attributes that influence risk perceptions, researchers have suggested that lay judgments of risk reflect two main dimensions, the extent to which the hazard is perceived to be known or unknown and the extent to which it is dreaded or not (Slovic, 1987). Because of the dread associated with significant hazards such as nuclear accidents, people often misperceive that there is a negative correlation between the

magnitude of risk and the extent of benefit, when in fact the correlation is positive (Slovic et al., 2004).

Leventhal and colleagues suggest that each person copes with illness threats in accord with their own 'common sense' model of that illness (*see* Illness Behavior and Care-Seeking). These models involve five attributes: the identity of the risk, its timecourse (e.g., chronic vs acute), its consequences, its causes, and its potential cure or control (Leventhal et al., 1992).

The preceding perspectives emphasize various hazard attributes. Another approach emphasizes the interconnections among the hazard properties. Beliefs about the cause of an illness, its prevalence, routes of exposure, and personal risk are all important, but it is also important to know how they are related to one another. Misunderstandings about the causes and prevalence of hazard, for example, may result in misperceptions about the likelihood of victimization. These different aspects of knowledge and belief are viewed as a 'mental model' that describes both the separate pieces and the connections between these pieces (Bostrom et al., 1992).

Hazard Probabilities

Much attention has been given to how people think about hazard probabilities. (Apparently researchers think that hazard severity is a simpler issue, for this topic has received little attention.) Although proportions (e.g., '0.25'), percentages (e.g., '25%'), frequencies (e.g., 25 out of 100), and odds (e.g., '1 in 4') are the units used by scientists to measure probability; there is abundant evidence that laypeople often have great difficulty understanding and using such information. For instance, people sometimes give a higher numerical estimate to the likelihood of *dying* of breast cancer than to the *likelihood* of developing breast cancer. Thus, the ability to recite the correct percentage, rate, or odds should not be used as the criterion to decide whether people truly understand the probability. Except for percentages given in weather forecasts, the public is rarely exposed to probability statistics, so it is not surprising that many people find numerical information about hazard probabilities unhelpful.

Some evidence indicates that people find verbal designations of probability (e.g., 'small chance of happening') to be easier to use and to better reflect their own views than numerical risk measures (Diefenbach et al., 1993), but people vary greatly in the numbers they associate with particular verbal labels, making the conversion of numbers to words highly subjective. Expressions of probability in terms of odds (e.g., 1 in 50 chances) are especially disliked by laypeople.

Because it seems impossible to navigate an uncertain world without forming estimates of the likelihood that particular events will occur, we tend to assume that people must form and encode judgments of hazard probabilities. In fact, it is possible that people rarely do encode such information. Instead they may generate risk judgments from past experiences and from their own implicit theories as needed. It is also possible that people store in memory only very crude probability information (e.g., no chance, small chance, large chance, certain) and never use the finer distinctions that preoccupy scientists and policy makers.

Because social comparison is a central feature of human existence, in everyday life people may find it more natural to make decisions on the basis of risk comparisons than on beliefs about absolute probability (the likelihood that an event will occur). Thus, a woman's interest in preventing heart disease may depend less on her beliefs about her absolute likelihood of a heart attack (e.g., 40% chance) than on her belief that her risk is greater than the risk of her friends, or even that her heart disease risk is less than her risk for other diseases.

Goals of Risk Perceptions

Obviously, accurate risk perceptions can help people make appropriate decisions about actions to avoid illness or injury. However, accuracy is only one of the goals guiding people as they formulate judgments about themselves, such as risk estimates (Kunda, 1990). Risk perception is not an unbiased appraisal of information, but an attempt to seek the most comforting view of one's personal vulnerability that fits within the bounds of the evidence. Beliefs about our vulnerability to harm can lead to positive or negative emotions (pleasure about successfully avoiding harm, anxiety about potential illness or disability). Perceptions of vulnerability can also affect our feelings of self-esteem. Because we want to believe that we are intelligent, competent, and foresighted, to admit that our actions place us at greater risk than our peers would be a threat to our self-esteem. Indeed, people are more likely to acknowledge their risk when they have a chance to reflect on their important values, thereby separating egoistic concerns from objective self-judgment (Harris and Epton, 2009). Thus, minimizing negative affect and maximizing self-esteem are also goals of risk perceptions, and these goals may be at variance with the goal to be accurate.

Optimistic Bias

Bias in risk perceptions is revealed especially clearly when people are asked to compare their risks with the risk of the rest of the population. This is typically done by asking people to indicate on a Likert-type scale how their risk compares with that of similar others (e.g., same age and sex), usually on a scale ranging from 'below average' to 'above average' with average as the midpoint. Sometimes people are asked on separate scales to estimate their own risk (e.g., from 'not at all likely' to 'extremely likely') and their peers' risk on separate scales, and a difference score is then computed; optimistic bias is present when the mean difference is less than zero. Using both types of measures, investigators have demonstrated that people often think their risk is lower than that of others (Weinstein, 1987). For example, when people are asked how their risk of a particular illness compares with the risk of others of the same age and sex, many claim to have below average risk and few admit to having above average risk. Across a variety of hazards, it is common to find 40–70% of a group asserting below average risk; another 30–50% saying that their risk is average; and less than 10% acknowledging that their risk is above average. Obviously, this distribution cannot be correct. The 'average' person has, by definition, an 'average' risk. So when the people who claim below average risk greatly outnumber those who say their risk is higher than average, implying that the average person is below average in risk, something must be wrong with their risk

judgments. It is interesting to note that people are often unrealistically pessimistic when estimating their absolute probability of experiencing hazards – for example, women greatly overestimate their risk of breast cancer – while being unrealistically optimistic about their comparative risk (e.g., Woloshin et al., 1999). Nevertheless, several (though not all) studies show that comparative risk perceptions may be more predictive than absolute risk perceptions of behavior, demonstrating that they are important to study (Klein, 1997).

Optimistic bias is not just denial, a blanket defense against anxiety. If it were, we would expect to find the greatest optimism among hazards, such as cancer, that generate the most fear. The amount of optimistic bias (that is, the extent to which people claiming below average risk exceed those who say their risk is above average) does vary from hazard to hazard (Weinstein, 1987), but it is not related to the severity of the hazard. Instead it is greatest for events that are believed to be preventable by individual action and events with which people have little personal experience. Bias is especially great if people think that vulnerability appears early, leading them to conclude that if they have not experienced the problem so far, they are free from future risk.

The belief that we are less at risk than others is apparently reassuring, since people resist attempts to correct their misperceptions. Most interventions designed to eliminate bias in comparative risk judgments – for example, having people think of the ways in which the negative event *could* happen or think of the precautions that they have *not* taken – have proved unsuccessful (Weinstein and Klein, 1995).

It may appear obvious that underestimating risk will expose people to unnecessary harm. Indeed, people who are unrealistically optimistic are less likely to worry about a hazard; learn about how to prevent it; and take adequate precautions, with downstream implications. For example, one study showed that people who where unrealistically optimistic about their risk of heart disease had higher levels of atherosclerosis (Ferrer et al., 2012) and another study showed the smokers who were unrealistically optimistic about their lung cancer risk had less interest in quitting (Dillard et al., 2006). However, a different view of this issue, known by the label 'positive illusions,' suggests that optimistic biases are really beneficial (Taylor and Brown, 1988). It points out that people who are overly optimistic about their ability to fight off the AIDS virus, for example, may be encouraged to maintain a healthy lifestyle and to bear with burdensome treatments. Thus, even if the perception of resistance is false, it may support other actions that are themselves beneficial. Although definitive evidence is lacking, it seems likely that underestimations of personal vulnerability decrease interest in prevention, especially when people see themselves as members of a group that does not need to be concerned about the risk, but optimism about surviving a life-threatening illness can help patients avoid depression and hopelessness (Wood et al., 1985).

Effects of Risk Perceptions on Health-Related Behaviors

Perceived probability and/or perceived severity occupy an important role in nearly all theories that are used to explain the health-related behavior of individuals (*see* Psychosocial Theories of Health Behavior). The literature on health behavior generally supports the idea that increases in perceived risk increase precautionary behavior (Brewer et al., 2007), but there are also numerous instances in which risk perceptions and behavior turn out to be unrelated.

This should not be surprising. There are many factors other than risk perceptions that influence behavior, and people who think that they have a high risk may nevertheless doubt their ability to carry out precautions or the efficacy of the precautions. In addition, most health behavior studies have used correlational research designs, which are problematic for examining risk perception–risk behavior linkages. Finally, as mentioned earlier, experimental interventions may fail to alter peoples' perceptions of their invulnerability.

The link between perceptions and action may depend on the type of action. Precautions that prevent a health problem from occurring (such as vaccinations) should reduce both perceived risk and worry about that risk. In contrast, being tested for the presence of an existing health problem (as in cancer screening) offers the immediate potential of extremely distressing information, especially if the problem is difficult to treat, so high perceived risk may be associated with high fear. The links between risk perceptions and different types of action still need to be elucidated.

Health Risk Perception

Abstract

Perceptions of health-related risks are a prerequisite for taking protective action, adopting a healthier lifestyle, attending health screenings, and adhering to medical care. It seems inherently plausible that the greater the perceived risk for one's own health is the greater the motivation for protective action. Accordingly, it is important to understand how people perceive health risks, how accurate these perceptions are, and how information about one's own health risk is received. This article focuses on general and personal risk perceptions, discusses the role of intuition in personal risk perception, and presents findings regarding reactions to individualized feedback about risk.

Introduction: Why Study Risk Perception?

Risk perception, i.e., how individuals think and feel about the risks they face, is an important determinant of protective behavior. For instance, responses to the A/H1N1 virus or 'swine flu' outbreak in 2009 showed that the success of public health intervention programs is largely dependent on individual risk perception. Although many governments launched large-scale vaccination campaigns, vaccine uptake in the general population was very low. In Germany, for example, only 6.8% of the general population followed the recommendation to be vaccinated, even though vaccination is the most effective intervention for preventing influenza and A/H1N1 (Renner and Reuter, 2012).

Accordingly, it seems inherently plausible that people not only need to be aware of an existing health risk ('Many people are becoming infected with a new type of influenza.'), but they also need to feel personally at risk ('I might catch the new influenza myself.') in order to take protective action. It is thus critical to understand (1) how people construe and evaluate health risks in general (general risk perception), (2) how they gauge their own personal risk (personal risk perception), and (3) how they react to information indicating that they are personally at risk.

General Risk Perception

Risk Assessment and the Numbers of Risk

Risk is commonly defined as a multiplicative combination of the probability of a hazardous event occurring (e.g., smoking) and the severity of the resulting negative consequences (e.g., lung cancer). This definition of risk, as 'probability × severity,' implies that greater probability and greater severity result in greater overall risk (Slovic, 2000).

Numerically determining the probability of adverse events and possible adverse consequences is one of the main challenges for scientific *risk assessment* (Slovic, 2000). Risks to health can be assessed on the basis of different metrics, such as morbidity and mortality rates (number of cases of disease or deaths per year). For example, there were 2 426 264 deaths in the United States in 2006. While heart diseases led to 631 636 deaths in the United States in 2006 (26%), accidents were responsible for 121 599 deaths (5%) (Heron et al., 2009). Thus, heart diseases posed a five times greater risk in comparison to accidents. Moreover, the magnitude of risk can be framed in many numeric formats, such as natural frequencies (e.g., 5 out of 100), percentages (e.g., a 5% chance of contraction), or probabilities (e.g., 0.05), and in many different visual formats (e.g., bar charts, pie graphs, or icons displaying the number of individuals affected). All of these numeric formats are equally valid representations of 'the numbers of risk' in the realm of risk assessment.

In contrast to 'risk assessment,' 'risk perception' considers how people, in particular laypeople, construe risk. Wright et al. (2002) examined risk judgments made by experts (life insurance underwriters) and laypeople (business students) for 31 hazards (smoking, asthma, etc.) and compared them to the actual risk level (annual fatalities). The correlation between risk judgments and factual risk for fatalities was $r = 0.66$ for the experts and $r = 0.73$ for the laypeople. Thus, both laypeople and experts were capable of ordering the hazards by the absolute risk level in the metric of annual fatalities. However, the accuracy of lay perceptions commonly decreases when it comes to estimating more complex numbers of risk, and systematic deviations between risk assessment and lay risk perception occur (see for further discussion Gigerenzer et al., 2008; Renner and Schupp, 2011).

How well risk statistics are understood depends on numeracy, i.e., the ability to process basic numerical and probability concepts (Reyna et al., 2009). As expected, highly numerate adults are more likely to extract and use appropriate numerical principles and thereby have more complete and complex information than less numerate individuals. Furthermore, the issue of which type of numeric and visual formats facilitates accurate perceptions of risks has been addressed by many studies (Gigerenzer et al., 2008). One of the most striking effects emerged from the comparison of relative and absolute numeric risk formats. Relative risk formats describe risk in conditional probabilities, percentages, or ratios without defining the baseline or absolute risk level. Thus, a risk factor may be described as conferring '50% more risk' than another, even when the absolute increase is only from 2 to 3%. Without information on the baseline risk level, people tend to overestimate not only the impact of risk factors but also the impact of precautionary measures. Furthermore, conveying risk in

natural frequencies (e.g., 5 out of 1000 instead of 0.5%) facilitated the understanding of risk within laypeople (cf also Ferguson and Starmer, 2013; Gigerenzer et al., 2008). Thus, the pessimistic view that the public is not capable of understanding the numbers of risk may at least partly be the result of using suboptimal formats when communicating risk. Sensible risk communication should ideally present an array of risk information, i.e., absolute and relative risk information, mortality rates, and survival rates, as well as natural frequencies, in order to increase risk literacy in laypeople and experts over time.

How People Construe Risk: The Multidimensionality of General Risk Perception

Risk assessment can be seen as an objective approach to determining risk, which commonly considers two core components: the severity of the negative consequences and the probability of an occurrence of a hazardous event. However, numerous studies suggest that risk perception in the layperson is more complex, and that it is influenced by risk characteristics other than 'probability' and 'severity.' The issue has been most thoroughly examined with respect to the psychometric paradigm, which provides a systematic attempt to determine the characteristics associated with risk.

The Psychometric Paradigm

A pioneering study by Fischhoff et al. (1978) examined risk perceptions of various hazards, which were evaluated in terms of several risk attributes. Factor analysis was used to condense ratings of risk attributes into two orthogonal dimensions of 'dread' and 'unknown risk.' The factor 'dread' captures aspects such as perceived control over exposure to the risk, the degree of catastrophic consequences, or global ramifications. The factor 'unknown risk' refers to the degree to which a risk is predictable, observable, and understood. The psychometric paradigm plays a prominent role in risk perception research and numerous studies have confirmed the two factors, 'dread' and 'unknown risk' (see Sjöberg et al., 2004, for a review). Overall, despite noted shortcomings (e.g., Sjöberg et al., 2004), this work constitutes a landmark in risk perception research by showing that characteristics beyond the 'probability' by 'severity' calculus influence public perception and attitudes toward risk.

Intuition and Feelings in Risk Perception

The factor 'dread,' identified by research using the psychometric paradigm, clearly alludes to emotional characteristics. However, emotions were seldom discussed explicitly in earlier theories of risk perception. This has now changed and emotion has become a key area of risk perception research. For instance, Loewenstein et al. (2001) propose that emotional feelings can affect risk perceptions independently from numerical cognitions (probability, severity) or other attributes of risks (e.g., controllability, catastrophic potential). Similarly, Slovic and Peters (2006) distinguish between an intuitive mode of risk perception based on feelings and the rational, deliberative analysis of risk. Both approaches share the notion that feelings of risk stem from rapid and largely automatic routines that reflect an association-based, parallel mode of thinking, which is often referred to as 'intuition.' In contrast, the so-called 'rational' mode of risk analysis is presumed to depend on resource-dependent, effortful, and serial processes (see also Pachur et al., 2012).

One challenge for examining intuitive risk perception is that rapid and largely automatic processing is hard to capture. Neuroimaging methods, such as functional magnetic resonance imaging (fMRI) and event-related potentials (ERPs), allow measuring of rapid, introspectively opaque, and affectively charged processes and may accordingly be useful in examining the intuitive processes involved in risk perception. A series of ERP studies on HIV risk perception (e.g., Renner et al., 2012; Schmälzle et al., 2011, 2012) provides an example of this novel approach. Previous research using focus groups and retrospective interviews with HIV-positive people had revealed that people have spontaneous impressions of risk – i.e., they often reported that they were convinced that their partners were safe. These impressions about a potential partner's HIV risk may make people prone to rely on 'illusory control strategies,' such as selecting 'safe-looking' partners. To uncover the mechanisms behind these intuitive HIV risk perceptions, neural responses were measured while participants spontaneously evaluated the HIV risk of unacquainted individuals depicted in photographs. Demonstrating the fast and frugal risk perception mode, ERPs reliably differentiated between individuals perceived as risky and safe early in the processing stream (e.g., Schmälzle et al., 2011). The early onset of this electrocortical differentiation (<300 ms) precedes systematic reasoning about health risks and supports the notion of intuitive as opposed to analytic processing. Furthermore, the late positive potential (LPP), a specific ERP component that has been linked to affective evaluation processes, was also associated with HIV risk perception. In particular, individuals perceived as risky elicited larger LPPs compared to individuals perceived as safe (see **Figure 1**; Schmälzle et al., 2011). These findings were corroborated by fMRI measurements, which revealed that individuals perceived as risky activated regions of the saliency network, i.e., the anterior insulae and medial frontal cortex, which are also engaged by threatening and negative-affect-related stimuli (Häcker et al., 2014). Based on these findings, when people report that they 'just know' the risk posed by a certain individual, their feeling of risk may reflect the implicit assessment of personal characteristics related to a HIV risk stereotype. Extrapolating from this line of research, the integration of experimental methods, i.e., self-reports, behavioral observation, and psychophysiology, seems highly promising for uncovering the intuitive sensing of health risks.

Personal Risk Perceptions

At first glance, it seems obvious that perceiving a health threat is a prerequisite for the motivation to change a risk behavior. However, from a psychological perspective, the process is far more complex: people not only need to know about the existence of a health risk (general risk perception; e.g., 'Many people are becoming infected with a new type of influenza.'), but they need to feel personally at risk (personal risk

perception, e.g., 'I might catch the new influenza myself.') in order to take protective action. In general, two different types of personal risk perceptions are distinguished: (1) absolute personal risk perceptions and (2) comparative personal risk perceptions (Renner and Schupp, 2011; Shepperd et al., 2013; see also Table 1).

Absolute Personal Risk Perceptions

One of the most common ways of assessing people's perception of their own health risks is to ask them to estimate their personal absolute risk in numerical form ('My risk of catching the new influenza this winter is 70%.'). Comparing personal absolute risk perception with epidemiological or actual risk estimates shows that they often greatly deviate. Similar to general risk perceptions, the likelihood of contracting a disease is often drastically overestimated. Lipkus et al. (2001), for example, asked adult women between the ages of 45 and 54 years to estimate their lifetime breast cancer risk. In addition, they measured the actual breast cancer risk using the Gail score, which calculates breast cancer risk on the basis of seven risk factors (e.g., age, race, age at menarche, age at first live birth, number of first-degree relatives with breast cancer). On average, compared to their actual lifetime risk (8%), the women greatly overestimated their lifetime breast cancer risk (34%), indicating an unrealistic pessimistic bias in absolute personal risk perception at the group level (see Table 1).

Comparative Personal Risk Perceptions

Although people often overestimate their personal absolute risk, they are often convinced that their risk is lower than that of other people. The same women who overestimated their personal absolute breast cancer risk in the study by Lipkus et al. (2001) were convinced that their comparative risk was below average (see Table 1). Numerous studies have shown that when people are asked to rate their chances of experiencing certain illnesses, and other problems, most of them report their risk is below average (see Shepperd et al., 2013). However, if people believe on average that their risk is below average, they are systematically underestimating their personal risk. This bias in comparative personal risk perception has been labeled *unrealistic optimism* or *optimistic bias* (Perloff and Fetzer, 1986; Weinstein, 1980). Unrealistic optimism has been demonstrated for men and women across age-groups and education levels (see Renner and Schupp, 2011; Weinstein, 2003).

It is important to note that the 'classical unrealistic optimism' only indicates a bias in comparative personal risk perceptions at the level of the group (see Table 1). A woman who says that her breast cancer risk is 'below average' might

give a somewhat optimistic risk rating, but if she has a low risk factor profile, her optimistic rating may actually be a realistic perception of her risk status (cf Weinstein, 2003). To assess the optimistic bias at the individual level, objective risk measures are required such as ‘health risk appraisals’ that estimate a person’s actual risk based on characteristics such as medical history, blood pressure, smoking habits, and epidemiological data (e.g., CVD Framingham Risk Score at http://cvdrisk.nhlbi.nih.gov).

Why do people feel less at risk than others? Research has posited various explanations for this intriguing phenomenon, involving both motivational and cognitive processes. Motivational accounts postulate that the optimistic bias is fueled by the motivation either to self-enhance or protect, and maintain a positive view of one’s health. However, a purely motivational account cannot sufficiently explain this phenomenon. If people predominantly bias comparative risk perceptions because they want to maintain a positive self-view, serious diseases should provoke an increased degree of optimistic bias because they are particularly threatening to the self. Contrary to the idea that biased comparative risk perceptions are a defense against feelings of threat and anxiety, unrealistic optimism is generally no greater for serious, life-threatening hazards than for more mundane problems (Harris et al., 2008).

Interestingly, some hazards appear to be associated with a strong and reliable comparative optimistic bias (e.g., STDs, alcohol problems), whereas other hazards commonly elicit only a weak or no bias (e.g., colds, cancer). A seminal study by Neil Weinstein (1980) observed that unrealistic optimism was pronounced when the hazard was perceived as controllable and associated with a vivid victim stereotype. People find it easier to picture stereotypical victims of controllable events (Hahn and Renner, 1998; Perloff and Fetzer, 1986; Thornton et al., 2002). For example, lung cancer is perceived as a controllable and behavior-dependent disease, and people can easily picture a typical victim (Hahn and Renner, 1998). This may explain why lung cancer typically elicits a pronounced unrealistic optimism, whereas cancer in general does not. The less similar a person believes he or she is to the high-risk stereotype, the safer the person will perceive him- or herself to be (Perloff and Fetzer, 1986; see Renner and Schupp, 2011).

One intriguing conclusion from this research is that public health education campaigns may often facilitate, instead of reducing, unrealistic optimistic risk perceptions. The guiding principles proposed by campaigns for health risk reduction usually include vivid presentations of risk factors and show high-risk persons. This may foster risk stereotypes that are perceived as dissimilar and thereby may lead to an underestimation of personal risk if individuals think that many risk factors do not apply to them. Consequently, risk communication that only provides information about general risk may make people aware of a risk (‘Smoking causes coronary heart disease.’) but also lead to an underestimation of self-risk (‘It is unlikely that this will happen to me.’) by creating high-risk stereotypes. Accordingly, providing information about an individual’s

personal risk status should be less ambiguous and more effective for facilitating realistic personal risk perception and protective behavior.

Reactions toward Personalized Risk Feedback

In recent years, health risk assessment tools have been developed to assess individual risk for particular diseases. For example, the National Institute of Health in the United States offers an online tool for estimating the 10-year risk of having a heart attack (http://cvdrisk.nhlbi.nih.gov/). The increasing availability of such services over the Internet and the rise of over-the-counter testing kits underscore the need for a better understanding of how individuals react to such feedback. In an agenda-setting study, Jemmott et al. (1986) devised an experimental paradigm that enables the study of reactions toward personalized health risk feedback. Participants who were led to believe that they suffered from a hypothetical thioamine acetylase (TAA) deficiency perceived their test result as less accurate and rated TAA deficiency as a less-serious health threat when compared to the non-TAA group (for a review, see Croyle et al., 1997). The reduced acceptance of negative health risk information compared to positive one is a very robust phenomenon, evident across a wide range of diseases and samples (for an overview see Ditto, 2009; Renner and Schupp, 2011).

The Motivated Reasoning Perspective

Why is bad news less accepted than good news? The lower acceptance of negative health risk feedback than positive one is commonly seen as clear-cut evidence for 'self-defensive denial' or 'motivated reasoning' (e.g., Croyle et al., 1997; Helzer and Dunning, 2012; Kunda, 1990; McQueen et al., 2013). People who are informed having an elevated risk of disease appear to derogate the validity of the risk factor test in order to maintain a favorable sense of their health. At first glance, the motivated reasoning account, which proposes self-defensive denial in information processing, poses a straightforward explanation for the frequently observed asymmetrical acceptance pattern: people do not like bad news; consequently, they try to derogate it with superficial rational strategies. However, several limitations, such as the 'adaptive paradox,' have been noted (cf Ditto and Lopez, 1992; Renner and Schupp, 2011; but see McQueen et al., 2013). If the predominant response to threatening information is self-defensive denial, recipients should not see a need for adaptive action and protection, ultimately resulting in serious harm. In contrast, studies assessing intentions and behavior change commonly report adaptive responses instead of the predicted unresponsiveness to information that signals a health threat (e.g., Shiloh et al., 2013; see for a review Sheeran et al., 2013).

The Quantity of Processing Perspective

In an attempt to explain the asymmetrical acceptance of health risk information, Ditto and Lopez build upon the principle that negative information generally has greater impact than neutral or positive information (1992; for a review see Ditto, 2009). Their quantity of processing (QOP) view draws upon the fact that negative information triggers more elaborate cognitive analyses than positive information does. The more deeply people think about negative information, the more likely they are to consider plausible alternative explanations, producing greater uncertainty regarding the validity of the information. As a consequence, negative information is less likely to be accepted than positive information. Supporting this notion, participants who received negative TAA feedback accepted low-quality feedback less readily than high-quality TAA feedback. Moreover, while positive feedback was highly accepted regardless of whether it was of high or low quality, participants only accepted negative information to a similar degree when they believed the information was high quality (Ditto et al., 1998). These results are in line with the QOP view that negative risk information triggers more elaborate processing than positive risk information does, and that negative information is, therefore, less likely to be accepted than positive information (see also Mata et al., 2013). However, from a motivational reasoning perspective, one could argue that people receiving highly valid, negative TAA risk feedback only accepted it because there was virtually no leeway for derogating the information. Thus, it remains unclear whether the unambiguous acceptance of good news or differential acceptance of bad news indicates an adaptive or self-defensive denial reaction pattern.

The Cue-Adaptive Reasoning Perspective

It is commonly assumed that positive health risk feedback such as "Your lifetime risk for developing colorectal cancer is 10:10,000" is met with great acceptance and reassurance (Wardle et al., 2003). Curiously, this seems not always to be the case. Weinstein et al. (2004) examined primary care patients between 40 and 70 years of age who received computerized risk assessment feedback about their colon cancer risk. For most patients, the risk feedback indicted a lower risk status than they had expected (average actual risk: 10:10.000 vs average perceived pretest risk: 146:10.000). According to the motivated reasoning and QOP views, receiving such good news should have resulted in pronounced acceptance of the feedback. However, an opposite pattern of result emerged: post-feedback-perceived risk was in many cases still substantially higher than the actual risk, indicating that people often distrusted their personalized risk feedback. Similar resistance toward positive feedback or 'lack of reassurance' has been observed in various empirical studies (e.g., Dillard et al., 2006; Linnenbringer et al., 2010). One might argue that the personalized risk feedback was difficult for the recipients to understand and thus, the findings do not indicate a lack of reassurance but rather a lack of understanding. However, in an experimental study using personalized risk feedback about a (fictitious) fatigue syndrome, Gamp and Renner (manuscript submitted for publication) found a similar lack of reassurance after positive information in post-feedback-perceived risk. Conversely, post-feedback risk for an average peer was accurately adapted to the given peer risk feedback score. Hence, people are generally capable of

understanding risk information and adapting their risk estimations accordingly. This raises the question, when and why do people resist self-related positive health risk feedback?

The cue-adaptive reasoning account (CARA) assumes that both negative feedback and risk feedback, which conflicts with preexisting risk perceptions, serve as cues that draw attentional resources for more elaborate processing (Panzer and Renner, 2009; Renner, 2004). If people spend more cognitive resources on negative or unexpected risk information, plausible alternative explanations are more likely taken into account. This, in turn, increases the likelihood that negative or unexpected risk information is perceived as being less valid and as a consequence it is less likely to be accepted than expected positive risk information. One important implication of this reasoning is that not only unexpected bad news, but also unexpected good news is received with greater reluctance. Data from a community cholesterol screening (Renner, 2004; see also Gamp and Renner, manuscript submitted for publication) showed that participants who received unexpected or expected negative risk feedback were sensitive to the quality of the given feedback. Indicating more elaborate information processing, feedback acceptance was significantly higher for high-quality risk feedback than low-quality (see **Figure 2**). Importantly, participants receiving unexpected positive risk feedback also showed sensitivity to feedback quality, and low-quality feedback was rated as less accurate than high-quality. The only group that was not sensitive to the quality of the feedback was the group that expected and received positive risk feedback information. This group accepted the given feedback independently of the quality. A similar pattern was also found for behavioral-proximal measures.

The assumption that unexpected good news also receives deeper processing might first seem counterintuitive. However, especially in the context of personally consequential feedback, it represents an adaptive response because accepting false 'all-clear' health risk feedback could result in the refusal or cessation of prophylactic measures. In this case, resources previously invested in preventive actions would be expended, while severe harm would not be prevented by protective action. Accordingly, the CARA view conceptualizes both, the lack of reassurance following unexpected positive health risk feedback and the asymmetrical acceptance of negative versus positive risk feedback as an unintentional by-product of the adaptive allocation of cognitive processing resources.

Conclusion

It is widely agreed that people's understanding of health risks is of central relevance for effective risk communication and health interventions. Being aware of health risks is certainly a precondition for accurate risk perception. But even when people are aware of a risk (general risk perception), this does not mean that they regard themselves as personally at risk (personal risk perception). Public health interventions portraying people at high risk may foster high-risk stereotypes and, as a consequence, induce a paradoxical effect: people might be well informed about the magnitude of the risk but at the same time they might be convinced that this misfortune will not happen to them because they feel highly dissimilar to the high-risk stereotype. Thus, although general risk perceptions might be substantial, personal risk perceptions might be low and optimistically biased. Research on personal risk perception has focused on absolute as well as comparative aspects of risk perception, and recent approaches adopted neuroimaging in order to shed light on the mechanisms of risk perception, whose nature is presumably less numerical and analytic, but rather more intuitive-experiential and affective. To cross the Rubicon between general and personal risk perceptions,

recipients should receive personalized risk information. However, personalized risk information is filtered through preexisting risk perceptions, and conflicting information is carefully scrutinized before it is accepted. Interestingly, this not only holds for negative risk feedback, but also applies to unexpected positive risk feedback. Therefore, to avoid increasing concern among participants or the need for retesting, an 'all-clear' nonelevated risk status should be as carefully explained and discussed as an elevated risk status health.

Health Self-Regulation, Motivational and Volitional Aspects of

Abstract

Health self-regulation refers to the motivational, volitional, and behavioral processes of abandoning health-compromising behaviors in favor of adopting and maintaining health-enhancing behaviors. The article addresses self-regulatory constructs and self-control models that examine how people resist temptations, persist at tasks, cope with adverse emotions, make choices, or overcome undesired impulses. A process model is described that suggests a distinction between preintentional motivation processes that lead to a behavioral intention (goal-setting phase), and post-intentional volition processes that lead to actual behavior (goal pursuit phase).

Introduction

Many health conditions are caused by risk behaviors, such as problem drinking, substance use, smoking, reckless driving, overeating, or unprotected sexual intercourse. The key question in health behavior research is how to predict and modify the adoption and maintenance of health behaviors. Fortunately, human beings have, in principle, control over their conduct. Health-compromising behaviors can be eliminated by self-regulatory efforts, and health-enhancing behaviors can be adopted instead, such as physical exercise, weight control, preventive nutrition, dental hygiene, condom use, or accident prevention. Health self-regulation refers to the motivational, volitional, and behavioral processes of abandoning such health-compromising behaviors in favor of adopting and maintaining health-enhancing behaviors (Mann et al., 2012).

Self-regulation, however, is a broader term going beyond the application to health behaviors and refers to all contexts where goal setting and goal striving are at stake. It is related to self-control, self-discipline, or willpower and applies to various domains of human functioning. In a general sense, self-regulation is a process that includes setting goals for oneself, what courses of action one chooses to pursue, how much effort one invests in given endeavors, and how long one perseveres in the face of barriers and setbacks. It encompasses reflective as well as automatic processes that guide goal-directed thoughts and behaviors in a more or less adaptive way.

Social–emotional–cognitive process models often distinguish phases of self-regulation and allocate persons in terms of their individual position within these phases. A useful distinction is the one between motivation and volition (Heckhausen and Gollwitzer, 1987). In the motivation phase, individuals are in a deliberative mindset while setting a goal (intention), whereas in the volitional phase, they are in an implementation mindset while pursuing their goal. Some health self-regulation theories are in line with such a process perspective (e.g., Bandura, 1997; Baumeister et al., 1994; Carver and Scheier, 1998; Kuhl, 2001; Mischel et al., 1996; Schwarzer, 2008). In such models, self-regulation is viewed as a multiphase process that involves a set of beliefs, expectancies, emotions, or actions.

As an alternative to the process view of self-regulation, some authors have identified specific constructs that may help to investigate how people engage in goal-directed actions, how they bring about desirable outcomes, or how they disengage from goals that appear unattainable. Whereas the social–cognitive self-regulation models are process based, perceived self-efficacy is a capacity-based belief and self-control is a capacity-based volitional strategy. Such constructs are viewed as personal resources that allow resisting temptations, modifying habits, and overriding impulses. With this capacity, individuals exert a conscious effort to alter their dominant responses to internal or environmental challenges.

In this article, we first discuss self-efficacy and self-control as self-regulatory constructs, and second we will describe a process-oriented self-regulation model that is mainly applied to health behavior change.

Self-Regulatory Constructs and Models

Perceived Self-Efficacy

Perceived self-efficacy portrays individuals' beliefs in their capabilities to exercise control over challenging demands (Bandura, 1997). It involves the regulation of thought processes, affective states, motivation, behavior, or changing environmental conditions. These beliefs are critical in approaching novel or difficult situations, or in adopting a strenuous self-regimen. People make an internal attribution in terms of personal competence when forecasting their behavior (e.g., 'I am certain that I can quit smoking even if my friend continues to smoke'). Self-efficacy influences the challenges that people take on as well as how high they set their goals (e.g., 'I intend to reduce my smoking,' or 'I intend to quit smoking altogether'). Some people harbor self-doubts and cannot motivate themselves. They see little point in even setting a goal if they believe they do not have what it takes to succeed. Thus, the intention to change a habit that affects health depends to some degree on a firm belief in one's capability to exercise control over that habit.

Perceived self-efficacy has been found to be important at all stages of health behavior change (Bandura, 1997), but it does not always constitute exactly the same construct. Its meaning depends on the particular situation of individuals who may be more or less advanced in the change process. A distinction between action self-efficacy, maintenance or coping self-efficacy, and recovery self-efficacy is useful, because, over the course of health behavior change, different tasks have to be

 http://dx.doi.org/10.1016/B978-0-08-097086-8.26031-5

mastered, and different self-efficacy beliefs are required to do so successfully. For example, a person might be confident in his or her capability to be physically active in general (i.e., high action self-efficacy), but might not be very confident to resume physical activity after a setback (low recovery self-efficacy).

Action self-efficacy (also called 'preaction or task self-efficacy') refers to the first phase of the process in which an individual does not yet act, but develops a motivation to do so. It is an optimistic belief during the preactional goal-setting phase. Individuals high in action self-efficacy imagine success, anticipate potential outcomes of diverse strategies, and are more likely to initiate a new behavior. Those with less self-efficacy imagine failure, harbor self-doubts, and tend to procrastinate.

Whereas (pre)action self-efficacy is instrumental in the motivation phase, the two following constructs are instrumental in the subsequent volition phase and can, therefore, also by summarized under the heading of 'volitional self-efficacy' that supports goal pursuit. *Maintenance* (*coping*) *self-efficacy* represents optimistic beliefs about one's capability to cope with barriers that arise during the maintenance period. A new health behavior might turn out to be much more difficult to adhere to than expected, but a self-efficacious person responds confidently with more adaptive strategies, more effort, and prolonged persistence to overcome such hurdles.

Recovery self-efficacy addresses the experience of failure and recovery from setbacks. If a lapse occurs, individuals may attribute their lapse to internal, stable, and global causes; dramatize the event; or interpret it as a full-blown relapse. High self-efficacious individuals, however, avoid this effect by attributing the lapse to an external high-risk situation and by finding ways to control the damage and to restore hope. Recovery self-efficacy pertains to one's conviction to get back on track after being derailed.

There is a functional difference between these three self-efficacy constructs, whereas their temporal sequence is less important. Different phase-specific self-efficacy beliefs may be harbored at the same point in time. The assumption is that they operate in a different manner. For example, recovery self-efficacy is most functional when it comes to resuming an interrupted chain of action, whereas action self-efficacy is most functional when facing a novel challenging demand. This distinction between phase-specific self-efficacy beliefs has proven useful in various domains of behavior change (Luszczynska and Schwarzer, 2003; Ochsner et al., 2013; Renner and Schwarzer, 2000). Action self-efficacy tends to predict intentions, whereas maintenance (coping) self-efficacy tends to predict behaviors. Individuals who have recovered from a setback obviously need different self-beliefs than those who have maintained their levels of activity.

Self-Control

Self-control is a capacity-based volitional strategy that is related to self-efficacy beliefs. People are more inclined to resist temptations, modify habits, and override impulses if they believe they can do it. With this capacity, individuals exert a deliberate effort to alter their behavioral responses such as emotions, thoughts, or impulses. More than four decades ago, Walter Mischel and collaborators studied self-control in children which became the groundwork for today's research (Mischel et al., 1996). The children were offered sweets either right now or twice the amount later. Being able to wait for the more generous reward was taken as an indicator for self-regulatory success. Children who earned more by waiting turned out to be better adapted a decade later in school and at home. Thus, deliberate delay of gratification has been shown to be a powerful strategy to cope with impulsive tendencies. However, self-control is not merely waiting passively for a delayed gratification. It is an active problem-solving strategy, as children have found diverse ways of distraction from the tempting sweets in front of them. Sacrificing immediate pleasures in the service of attaining long-term desirable outcomes is a basic paradigm of self-regulation. Mischel and coworkers have developed a 'hot-and-cool' framework to account for individual differences in self-control. The cool system is reflective in nature where people contemplate their perceptions, goals, and actions. This represents the executive function. On the other hand, the hot system is emotional and impulsive, allowing people to respond intuitively and rapidly to tempting or challenging environments. If a hot stimulus overrides the cool system, immediate impulsive action follows, and self-control fails. There are individual differences in the susceptibility to hot stimuli, and such differences are relatively stable. In other words, the 'hot-and-cool' framework serves not only an experimental paradigm for self-regulation but is also related to a dispositional view of self-control.

Such dual-process models have been put forward by a number of authors. For example, Strack and Deutsch (2004) have suggested a reflective–impulsive model proposing that behavior is a joint function of reflective and impulsive processes. The reflective system activates behavioral schemata based on cognition such as deliberate balancing of pros and cons, awareness of personal goals, and social evaluation. In contrast, the impulsive system is a faster, less conscious, or automatic one, that activates an effortless motivation to approach or avoidance when confronted with a demanding situation. A conflict between the reflective and the impulsive systems may occur, for example when there is a spontaneous (impulsive) approach toward sweets that becomes overruled by a separate goal-consistent controlled (reflective) approach toward a carrot. Temptations are governed by impulsive processes whereas inhibiting temptations is governed by reflective processes. The former operate quickly, effortless, and automatically whereas the latter operate slowly and deliberately, requiring sufficient cognitive resources. The impulsive system is more oriented toward the present needs whereas the reflective system is less situation-dependent and rather guided by long-term personal goals (see also the temporal self-regulation theory by Hall and Fong, 2007). These processes are resource-based which means that low resources lead to an increased likelihood for impulsive processes to prevail because such processes can operate outside of awareness (Hofmann et al., 2009). Being successful or not in fighting off the tempting impulses depends on one's attentional resources and conscious coping abilities. As long as the necessary resources are available, the reflective system can overrule the tempting impulses.

The strength model of self-control (Baumeister et al., 1994) regards self-control as a finite resource that can be exhausted if

expended or overused. According to this view, self-regulation requires strength that can be equated with what is commonly called willpower. This self-control energy allows people to resist temptations, persist at tasks, cope with adverse emotions, make choices, or overcome undesired impulses. However, when they do so, they deplete their reservoir of limited resources. When this happens, failure on a subsequent, unrelated task requiring self-control is more likely. This drop in willpower has been called 'ego depletion': Self-control is seen as analogous to a muscle that also requires energy to exert force over a period of time (Muraven and Baumeister, 2000). Effortfully inhibiting tempting impulses depletes cognitive and motivational resources. Once depleted, subsequent efforts to resist temptation are less successful because self-control is a global, limited resource that relates to different domains of human functioning. Depletion is not just a matter of fatigue but various beliefs, mood, and attitudes might affect one's ability to resist temptation and control one's desired path of action. Experimental research has attempted to identify factors that manage to prevent ego depletion including manipulating levels of fatigue, changing expectancies for task performance, forming action plans, or stimulating the organism by glucose supplementation. A meta-analysis of 83 studies examined the effects of ego depletion on various kinds of outcomes, investigated moderators of such effects as well as alternative explanations, providing support for the strength model of self-control (Hagger et al., 2010).

Self-regulation of attention and emotion might also be seen as a stable personal disposition, an individual's characteristic that enables habitual control over recurrent actions, as well as in the process of behavior change (Mischel et al., 1996). As the reflective system can transcend tempting situations only if control resources are available, then these resources may have a dispositional basis. In line with this assumption, psychometric tools were developed that tap the trait dimension of self-control. For example, the self-control scale (Tangney et al., 2004) assesses people's ability to override or change inner responses (e.g., 'I get carried away by my feelings'; reversed) and to interrupt undesired behavioral tendencies and refrain from acting on them (e.g., 'I am good at resisting temptations'). The self-regulation scale by Schwarzer et al. (1999) refers to post-intentional self-regulation when individuals are in the phase of goal pursuit, and face difficulties in maintaining their action. In such a maintenance situation it is required to focus attention on the task at hand and to keep a favorable emotional balance. Thus, attention regulation and emotion regulation are reflected in these scale items 'I stay focused on my goal and do not allow anything to distract me from my plan of action,' 'If an activity arouses my feelings too much, I can calm myself down so that I can continue with the activity soon' (Luszczynska et al., 2004).

A Process-Oriented Self-Regulation Model

In the following, a process model is briefly described that covers the goal setting as well as the goal striving phase of health self-regulation, called the health action process approach (HAPA; Schwarzer, 1992, 2008). Other social–cognitive models have been criticized mainly because of the so-called intention–behavior gap (referring to the frequent failure of intention to predict behavior). As a comprehensive self-regulation model, HAPA suggests a distinction between preintentional motivation processes that lead to a behavioral intention, and post-intentional volition processes that lead to actual behavior.

Motivation: The Goal-Setting Phase

Before changing their habits, people need to become motivated. This is seen as a process toward an explicit goal or intention (e.g., 'I intend to quit smoking this weekend'). Three constructs are considered to play a major role in this process: (1) risk perception, (2) outcome expectancies, and (3) self-beliefs.

Risk Perception

Perceiving a health threat seems to be the most obvious prerequisite for the motivation to replace a risk behavior. If one is not aware at all of the risky nature of one's actions, motivation would hardly develop. Usually, people are aware of some level of risk although the accuracy of their perception may be biased. When it comes to a comparison with similar others, one's view of the risk is somewhat distorted ('Compared to others of my age and sex my risk of getting lung cancer is low/medium/high'). This has become known as the 'optimistic bias.' Nevertheless, persons also acknowledge some degree of risk when confronted with objective data (health risk appraisal). There is a realistic component that keeps the positive illusions in leash. For example, smokers not only know that smoking can cause adverse health in others, they also perceive that they themselves are more at risk for lung cancer and other diseases than nonsmokers. Risk perception has two aspects: perceived severity of a health condition and personal vulnerability toward it. The first refers to the amount of harm that might occur, and the second pertains to the subjective probability that one could fall victim to that condition. Thus, it has been recommended that people should be informed about the existence of a health risk, and moreover, that they should imagine themselves as possible victims if they do not take the necessary precautions. Scaring people into health behaviors, however, has not been shown to be effective. In general, initial risk perception seems to be advantageous to put people on track for developing a motivation to change, but later on other variables are more influential in the self-regulation process, such as outcome expectancies, self-efficacy, and behavioral intentions. Risk perception in itself is insufficient to enable a person to form an intention. Rather, it may set the stage for a contemplation process and further elaboration of thoughts about consequences and competencies.

Outcome Expectancies

People not only need to be aware of the existence of a health threat, they also need to know how to regulate their behavior by understanding the contingencies between their actions and subsequent outcomes. These outcome expectancies are influential beliefs in the motivation to change (Bandura, 1997). A smoker may find more good reasons to quit than good reasons to continue smoking ('If I quit smoking then I will save money'). Similarly, positive outcome expectancies (e.g., 'If I exercise five times per week, I will reduce my cardiovascular

risk') are chiefly seen as being important in the motivation phase, when a person balances the pros and cons of certain behavioral outcomes. This imbalance does not lead directly to action but it can help to form an intention to quit. The pros and cons represent positive and negative outcome expectancies that are typical in rational decision-making. However, such contingencies between actions and outcomes need not be explicitly worded and evaluated; they can also be rather diffuse mental representations, loaded with emotions. Short-term outcome expectancies ('eating this chocolate now improves my mood') are in conflict with long-term ones ('not eating it helps me to stay slim'). Outcome expectancies are prospective whereas outcome experience is retrospective. The latter can generate the former when people develop habits, based upon good experience that further stimulates positive expectancies.

Self-Beliefs

Further, one needs to believe in one's capability to perform a desired action (perceived self-efficacy; e.g., 'I am capable of adhering to my exercise schedule in spite of the temptation to watch TV'). Perceived self-efficacy (as described above) operates in concert with positive outcome expectancies, both of which contribute to forming an intention. Both beliefs are needed for forming intentions to adopt difficult behaviors such as regular physical exercise or a dietary regimen. This is in line with the capacity-based approach to self-regulation. Whereas other indicators of capacity (e.g., willpower, dispositional self-control) are often understood as rather general constructs, self-efficacy pertains to a behavior-specific task, and it may fluctuate rapidly when facing imminent self-regulatory demands.

Volition: The Goal Striving Phase

Changing one's health behavior is considered to be a difficult self-regulation process. After people have become committed to a goal they need to prepare action and, later, maintain the changes in the face of obstacles and failures. Thus, goal setting and goal pursuit can be understood as two distinct processes that require self-regulatory effort. After forming an intention, the volitional phase is entered. When a person is inclined to adopt a particular health behavior, the 'good intention' has to be transformed into detailed instructions on how to perform the desired action. Once an action has been initiated, it has to be maintained. This involves self-regulatory beliefs, skills, and strategies such as planning, coping self-efficacy, and recovery self-efficacy. Additional volitional constructs, sometimes included in HAPA research, are action control (monitoring) and social support that may shield one's goal pursuit from distracting or tempting situations.

The volitional process can be subdivided into sequences such as planning, initiation, maintenance, relapse management, and disengagement. The adoption and maintenance of the health behavior is not achieved through an act of will but involves the development of self-regulatory skills and strategies. This embraces various means to influence one's own motivation and behaviors such as the setting of attainable proximal subgoals, creating incentives, drawing from an array of coping options, and mobilizing social support. Plans specify the when, where, and how of a desired action, and persons take initiative when the critical situation arises and perform preparatory behaviors. Action control processes include focusing one's attention on the task, while avoiding attention to distractors, resisting temptations, and managing unpleasant emotions. Perceived self-efficacy is required to overcome barriers and to stimulate self-motivation repeatedly. Once an action has been taken, individuals with high maintenance self-efficacy invest more effort and persist longer than those who are less self-efficacious.

Competent relapse management is needed to recover from setbacks. Some people rapidly abandon their newly adopted behavior when they fail to get quick results. When entering high-risk situations (e.g., a place where others smoke), they cannot resist due to a lack of self-efficacy. The competence to recover is different from the competence to initiate an action. Restoration, harm reduction, and renewal of motivation are serviceable strategies within the context of health self-regulation.

Disengagement from the goal can be evidence of lack of persistence and, thus, indication of self-regulatory failure (Carver and Scheier, 1998). But in the case of repeated failures, disengagement or scaling back the goal might become an option which can be adaptive, depending on the circumstances. For example, if the goal was set too high or if the situation has changed and become more difficult than before, it is often not worthwhile to continue the struggle. In the case of health-compromising behaviors, giving up is not a tenable option. Better self-regulatory skills have to be developed and unique approaches to the problem need to be taken. The experience of failure can be a useful learning experience to build up more competence, on the condition that the individual makes a beneficial causal attribution of the episode, and practices constructive self-talk to renew the motivation.

A large body of literature has emerged that supports the HAPA as a useful health self-regulation model for various health behaviors, as documented by the most recent research on sunscreen use (Craciun et al., 2012), vaccination (Payaprom et al., 2011), condom use (Carvalho et al., 2014; Teng and Mak, 2011), smoking cessation (Radtke et al., 2011), alcohol consumption (Murgraff et al., 2003), physical activity (Gellert et al., 2014; Parschau et al., 2014), oral self-care (Schwarzer et al., 2014), and healthy eating (Godinho et al., 2014; **Figure 1**).

Figure 1 Diagram of the Health Action Process Approach (Schwarzer, 2008).

The HAPA is designed as an open architecture framework that is based on the following principles rather than on a set of specific hypotheses. Developed in 1988 (Schwarzer, 1992) as a health self-regulation model, it was an attempt to integrate the theory of action phases (Heckhausen and Gollwitzer, 1987) with social–cognitive theory (Bandura, 1997), based on five principles:

Principle 1: Motivation and volition. The health behavior change process is divided into two phases. There is a switch of mindsets when people move from deliberation to action. First comes the motivation phase in which people develop their intentions. Afterward, they enter the volition phase.

Principle 2: Two volitional phases. In the volition phase, there are two groups of people: those who did not yet translate their intentions into action, and those who did. Thus, there are inactive as well as active persons in this phase. In other words, in the volitional phase one finds intenders as well as actors who are characterized by different psychological states. In addition to health behavior change as a continuous process, one can also create three categories of people with different mindsets, depending on their current location within the course of behavior change: preintenders, intenders, and actors.

Principle 3: Post-intentional planning. Intenders who are in the volitional preactional stage are motivated to change, but they do not act because they might lack the right skills to translate their intention into action. Planning is a key strategy at this point. It serves as an operative mediator between intentions and behavior.

Principle 4: Two kinds of mental simulation. Planning can be divided into action planning and coping planning. Action planning pertains to the when, where, and how of intended action. Coping planning includes the anticipation of barriers and the design of alternative actions that help to attain one's goal in spite of impediments.

Principle 5: Phase-specific self-efficacy. Perceived self-efficacy is required throughout the entire process. However, the nature of self-efficacy differs from phase to phase. This is because there are different challenges as people progress from one phase to the next one. Goal setting, planning, initiative, action, and maintenance all pose challenges that are not of the same nature. Therefore, (pre)action self-efficacy, maintenance (coping) self-efficacy, and recovery self-efficacy are being distinguished.

An overview of motivational and volitional processes in health behavior change is presented in the video that supplements this article.

Abstract

Health social work has been historically associated with environmental, sociopolitical, and economic context of the society. With the industrialization, urbanization, and global warming, health social workers are combating poverty, environmental degradation, natural disasters, and health inequity. Health social work in this article is defined as a subcategory of social work profession that includes medical social work and public health social work. Health social workers serve to humanize the health and social care system, emphasizing the importance of the holistic psycho-social-spiritual needs of individuals and groups when they experience distresses of illness, trauma, death, or disabilities across the life span. Health social workers practice in hospitals, communities, health departments, nongovernmental organizations, and international bodies. Advocacy, self-help, psychosocial education, and community organization are commonly adopted strategies of patient empowerment for health social workers. International organizations are active in promoting reform in the global environment so as to make the world a better place.

Overview of Health Social Work

Introduction

The development of health social work was closely linked to global development of social work in the Europe and North America through history. With the industrialization, urbanization, and global warming, health social workers are combating issues such as poverty, environmental degradation, natural disasters, and health inequity. They are increasingly specialized in providing support and services to specific disease groups and treatment interventions such as cancer and organ transplant in hospitals and clinics. Table 1 summarizes the three major categories in the field of health-related social work.

Definition

Health social work is defined as a specialization of social work that includes medical social work, rehabilitation social work, and public health social work. As rehabilitation social work can also be grouped under medical social work, this article will mainly discuss health social work under the context of medical social work and public health social work. The former primarily uses professional activities to help individuals, families, groups, or communities related to certain medical conditions to "restore, retain, and enhance" (Council on Social Work Education, 2009: 7) their well-being, while the later adopts "an epidemiological approach" (Practice Standards Committee, 2005: 4) to address social problems affecting health and social functioning.

Development and Transformation of Health Social Work

The Nineteenth and Early Twentieth Century

Health social work was initially developed in the nineteenth century in the United Kingdom (UK) and the United States (US) in response to the social needs. The first professional health care social workers were employed as 'hospital almoners' in UK. They took care of patients with disease-related, social, and family issues under the London Charity Organization Society (COS). In the US, the first social worker was hired in Massachusetts General Hospital in 1905 (Gehlert and Browne, 2006: 6–7). As the profession developed and matured, hospitals have remained a key source of employment for social workers (Table 2).

One of the major public concerns during the nineteenth century was urban poverty and related issues such as infectious

diseases. While the health almoners under COS focused on helping the poor, a group of settlement house workers were more active in promoting social reform, initiating the Settlement Movement (Hick, 2002: 41–42). The Settlement Movement first begun in London to assist young well-educated people to serve in poor neighborhoods and to provide moral models for social improvement (Payne, 2005: 37–39). It had quickly spread to countries such as Canada and the US and brought a broad range of development in vital aspects including education, political action, and youth work (Payne,

2005: 46–47). Some social workers became involved in initiatives to influence policy and legislation as they found the coverage of the Poor Laws in Britain to be insufficient in combating poverty during the Great Depression. At approximately the same period of time, there is also a need for the US to address issues such as poverty and unemployment, where community development programs naturally grew.

Occupational Social Work

With rapid industrialization and economic development, new workforce including women, minorities, and people with disabilities emerged in the nineteenth century. Occupational social work, also referred as industrial social work, started to develop in the 1970s, catering to the needs and protecting the rights of the working populations (Kurzman, 2008: 314). Programs were introduced to ensure needs of daycare, occupational safety, equal opportunity, and quality of life of workers are protected. Early occupational social work programs targeted at alcoholism, with funding largely coming in from the National Institute on Alcohol Abuse and Alcoholism. Nowadays, as the field gets more mature, occupational social workers respond to more needs, often in union counseling and advocacy programs in the US (Kurzman, 2008: 312). Their duties cover individual counseling with employees in need, training relevant staff for referrals to social services, initiating programs to promote health, and advising on affirmative action plan, especially when vulnerable populations are involved.

Global Scene

With the passage of time, health social work has gradually developed across the globe, in European as well as Asian countries (see **Table 2** for a summary of health social work development and world events). Professional social work organizations and training institutions began to emerge across countries such as UK, Europe, and North America. The colonization movements of these countries, together with the establishment of international philanthropic nongovernmental organizations (NGOs), brought health social work to other countries including Australia, India, Singapore, China, Taiwan, Africa, South America, as well as their other colonies in different parts of the world. The rapid development of health social work in countries such as Bulgaria, China, and Estonia slowed down, when the communist parties came to power in 1940s. The tasks of social workers to provide welfare and address social problems were taken over by socialist states (Payne, 2005: 72–75) and social development was prioritized over social work. Health social work did not regain its role and significance until the breakup of the USSR and Eastern Europe as well as the opening up of China and other communist regimes in the late 1980s to harmony, and integration of individuals and families in societies (Payne, 2005: 74).

Health Social Work and Environmental Challenges

At the dawn of the twenty-first century, social work profession increasingly realized the importance of environmental protection when large-scale natural disasters such as flood, forest fire, earthquakes, and volcano eruptions were seen everywhere across the globe as a result of climate changes and environmental degradation (Gray et al., 2013: 4). As early as in the 1970s, social workers started to take initiatives in environmental issues and showed interests that range from ecologic perspective to environmental justice movement (Gray et al., 2013: 11). More recently, social workers advocate for best practice and policies to reduce carbon footprint, preserving sources of clean water and forests, and raise global awareness about environment protection. The three leading social work organizations – International Association of Schools of Social Work (IASSW), the International Federation of Social Workers (IFSW), and International Council on Social Welfare (ICSW) – explicitly announced their support toward the extension of the UN Kyoto Protocol to protect the environment and to reduce the effect of climate change. They have also presented in UN conferences, such as the Climate Change Conference in Copenhagen in 2009 (Dominelli, 2012: 85–86).

Health Disparity and the Roles of Health Social Work

At the turn of the twenty-first century, health disparities are becoming an international problem for industrialized and industrializing societies. The World Bank recognized poverty and social disparity as major threats to social development in the contemporary era (World Bank, 2012). Low-income populations are less accessible to health care and social care. Industrialized countries such as the US, Canada, UK, and Finland invest more on health compared with industrializing countries such as Niger, Nepal, Kenya, and China (Karki et al., 2013: 214–215). The situation is clearly indicated by health indicators including tuberculosis (TB) prevalence, human immunodeficiency virus (HIV), and relation of life expectancy to health expenditure.

Poverty and the insufficient investment in health and social care have lead to a variety of health problems in industrializing countries. Over 2 billion people live on less than US$2 per day and they cannot even afford for the basic medical care. Malnutrition, infant deaths, neonatal deaths, and stillbirths are taking more than one-third of the lives of global newborns and putting 20 million pregnancies at risks (IFRC, 2011: 13). Battles against communicable diseases such as TB, hepatitis, malaria, simple bacterial infections, and diarrhea are on-going. HIV/AIDS, as a global epidemic, has brought tremendous challenges for children, youth, adults, and their families. The estimated population who are living with HIV worldwide is 40 million according to UNAIDS (Newman, 2008: 357).

Facing the challenging situations in health care, health social workers can take active roles in leading and coordinating the interdisciplinary healthcare team. For example, health social workers can assist in reducing infant deaths and pregnancy risk through mobilizing community health workers, midwives, and doctors to provide home visits and cost-effective interventions such as immunization, micronutrients, treatment for diarrhea, malaria, and acute respiratory infections, as well as improved prenatal and delivery care in the rural areas (IFRC, 2011: 13). They can help to fight against communicable diseases with the promotion of environmental cleanliness, health, poverty reduction, and gender equality. Moreover, they may also contribute to HIV testing, early intervention,

treatment adherence, case management, and care coordination, as well as research and community engagement (Newman, 2008: 360–361).

Health social work has been historically associated with environmental, sociopolitical, and economic context of the society. While psychosocial and environmental aspects of deprivation and trauma are often closely related to illness and death, physical illnesses can also elicit emotional distress, and socioeconomic relationship breakdowns such as divorce and bankruptcy may result in somatic problems. Health social workers play vital roles in providing direct services, as well as promoting advocacy in research and policy practices.

Major Areas of Practice

As shown in Table 1, medical social workers, rehabilitation social workers, and public health social workers are the three main categories of social workers working in the healthcare system in serving individuals, families, communities, and societies. The following discussion will be focused on the two of the three categories: medical social work and public health social work. Rehabilitation social work will be excluded from the following discussions as there is a section on social work and disability; besides it can also be regarded as one of the subcategories under medical social work.

Medical Social Work

Health social workers practice in hospitals, communities, health departments, NGOs, and international bodies. Health social workers serve to humanize the health and social care system, emphasizing the importance of the holistic psycho-social-spiritual needs of individuals and groups when they experience distresses of illness, trauma, death, or disabilities across the life span. Those serving in hospitals and clinics are known as medical social workers. In face of diseases and illnesses, patients often experience distress including anxieties about the tests before the diagnosis, worries about loss of income or functioning due to the disabling effects of illness and/or treatment, grief over the loss of health and sense of control over one's life, frustration over social discrimination due to physical disfigurement or intellectual limitations, and disorientation with the world and feeling overwhelmed by the sense of vulnerability.

Medical social workers work flexibly as case managers, service coordinators, patient advocates, health educators, counselors, family therapists, and pastoral and spiritual care providers in helping patients throughout their course of illness. They serve patients through assessment and enhancement of their bio-psycho-social functioning, discharge planning, case management, or group intervention to facilitate their adjustment to illness and loss, strengthening their support networks, connecting them with necessary community resources for rehabilitation and long-term adjustment to chronic illness or disabilities, and building of self-help and survivors groups. They also mobilize volunteers to serve as patients' advocates, peer counselors, and expert patients.

In addition to the multiple roles, medical social workers in hospitals often work closely with the medical teams and are also becoming increasingly specialized. Some of them specialized according to disease groups and target patient groups such as oncology, cardiology, gynecology, geriatrics, and pediatrics and some specialized by settings such as social workers in clinics, intensive care unit, hospice and palliative unit. Others specialized by tasks including prenatal diagnosis, genetic counseling, case management, organ transplant, and infection control.

There is increasing research evidence supporting the importance of health social work in the healthcare system. For instance, Egan (2010) summarized research evidence of effective social work interventions for five diseases and found that health social work brings multiple positive effects including improving patients' knowledge, adherence, and competence in disease management, while enhancing their quality of life and self-esteem. More recent evidence sheds light on the integrative approach toward health and social work practices, suggesting the use of Eastern health models of body–mind–spirit (IBMS) intervention such as Taichi and qigong exercises, massage, meditation, mindful practices, yoga, meaning-making, resilience training, and spirituality of suffering and growth through pain to enhance holistic wellness (Lee et al., 2009: 217). Evidence has also been accumulating for positive- and strength-oriented intervention programs on forgiveness, gratitude, generosity, compassion, social support, and transformation (John Templeton Foundation, 2010).

Medical social workers participate not only in providing direct services to individuals and families, they also advocate for social and legislature change. An example would be the social workers in oncology and palliative care. Apart from playing a vital role in meeting the needs of clients with life-limiting illnesses and their family members, they also engage in education, navigating through and advocating the medical and social systems (Blacker and Christ, 2011: 21–23).

Public Health Social Work

Public health has emerged to promote health by preventing, limiting, and stopping the spread of disease (Keefe and Evans, 2013). As one of the members of the multidisciplinary settings, public health social workers address health from a broader perspective (Practice Standards Committee, 2005: 4), focusing on promoting healthy lifestyle to individuals, families, and groups; preventing illness; and reducing unhealthy behaviors such as smoking, the use of drugs and alcohol, physical or sexual violence, promiscuity, gambling, drunk driving, self-harm, and suicide. In countries such as Canada, social workers are hired as 'health promoters' (Raphael, 2000: 356–357) to identify key factors for health, promote activities to improve individuals' health conditions, reduce high-risk behaviors, and evaluate program effectiveness.

Public health social workers adopt a community development approach to mobilize resources, cultivate collective problem-solving, as well as improve health and resilience among underprivileged groups. Raising awareness for disease prevention, health promotion, improvement in nutrition, and access to immunization can enhance social development of the society. The short-term voluntary program for at-risk mothers and newborns offered by a Philadelphia

interdepartmental collaborative in the US would be an excellent example. The program was established in response to the amendment for the Federal Child Abuse Prevention and Treatment Act, which mandates a system for the mothers who are identified to have used illegal drug during pregnancy. The Philadelphia Department of Human Services and Philadelphia Department of Public Health, Division of Maternal, Child and Family Health expected law changes at the state level, and they developed this home-based program to serve the mothers who have used illegal drugs during pregnancy to ensure their health and a healthy environment for the development of their newborn babies. Safety of children is the top priority in service delivery. With a clear protocol, social workers, behavioral health specialists, and nurses work with the mothers closely for assessment, brief intervention plans, and referrals as needed. Encouraging outcomes have been reported in terms of mothers' action plan and capability of parenting (Claxton et al., 2010: 291–303).

With the increasing concerns over environmental issues, public health social work also extends to green social work or environmental social work, to promote a healthy or harmonious relationship between people and environment. Social workers in this field seek solutions to protect the environment and to achieve sustainability (Dominelli, 2012: 15–16). Interdisciplinary interventions at multiple levels (Macro, Mezzo, and Micro) curbing the sources of environmental challenges, including but not limited to industrial pollution, overuse of natural resources, global warming, waste disposal, and disasters are essential. Gray et al. (2013) even proposed the needs to better understand the interactions between human society and the natural environment and to develop case studies on how models of effective practice can be established in this new area of health social work (Gray et al., 2013: 13–16).

Public Health Social Worker and Disaster

In addition to the 'preventive' environmental protection work, public health social workers also take part in managing natural disasters such as drought, frost, tsunami, landslide, extreme heat waves, and cold spells as well as 'man-made' disasters such as wars, terrorist attacks, as well as nuclear accidents and oil spills. Corruption and the socioeconomic–political oppression of women, religious, or ethnic minorities are creating large refugee populations as they escape from homes ruined by political instability and brutality. These disasters, often accompanied by physical, sexual, and spiritual violence can put large populations under post-traumatic disorders that may bear life-long consequences. Public health social workers are thus playing an important role in the humanitarian actions along with others in the disaster management team (Mathbor and Bourassa, 2012: 294). Social workers serving in disastrous areas are taking on rescue, support, and rehabilitation tasks to minimize the impact of disasters as well as political and societal conflicts on individuals and society. Witnessing forms of human suffering and emotional trauma, they also involved in the development of positive- and strength-oriented approaches such as reconciliation, restorative justice, and forgiveness and hope interventions to assist disaster-affected populations in moving on with life. One example would be the medical social workers in US Veteran Administration hospitals. While providing direct services in meeting the increasing needs of war veterans, they were also actively involved in the interdisciplinary teams in the areas of research and public health (Keefe and Evans, 2013: 11).

Public health social workers play pivotal roles in facilitating communication of rescue information and help victims to identify family members and in managing volunteers and rescue workers in collaboration with the disaster victims on temporary shelters while establishing daily routines and mutual help teams in transient resettlement sites. For example, during the mega Sichuan Earthquake in 2008, Chinese social workers, along with other professionals and volunteers, helped in organizing social and recreational activities for victims displaced from their home and work, mobilizing care for vulnerable populations such as disoriented older adults and persons with disabilities, re-establishing kindergarten and schools for children as well as play groups, facilitating economic activities of shops and cook food stalls plus other necessary services in temporary shelters so as to maintain a sense of normalcy. Self-management teams were also established for hygiene and sanitation. The involvement of social workers does not only provide immediate assistance in disasters management, but also empowered the community with the capacity and hope toward rebuilding their homes in the long run.

Ineffective management of natural or man-made disasters can lead to further disasters, such as an outburst of infectious diseases due to poor management of dead bodies. When large populations are moved into temporary housing or refugee camps, their access to a safe environment, clean water and food, sanitary facilities of waste, and refuse management become crucial. For example, the most common causes for death in Africa are diarrheal diseases, measles, acute respiratory infections, and malaria. Effective prevention includes protection from violence, disease control, immunization, case management, and maternal and child health care (Toole and Waldman, 1997: 283).

Disaster services have grown from treating Post-Traumatic Stress Disorder (PTSD) to "psychosocial capacity building" (Miller, 2012: 12). Public health social workers engage local partners so that culturally relevant and effective interventions can be developed with input from people and resources in disaster communities (Miller, 2012: 50). Evidence-based practice is highly recommended for application of previous lessons learned from emergent contexts, and evaluation processes are crucial to generate evidence for future reference. Handbooks in this field can be found to be referenced in Mathbor and Bourassa's article and they are particularly helpful in addressing the issues around collaboration in psychosocial responses in emergency settings.

Core Competencies

Despite the differences in duties and focuses, there are shared core competencies involved in medical social work (Council on Social Work Education, 2009) and public health social work (Practice Standards Committee, 2005). As in **Figure 1**, it is clear that medical social work and public health social work

Figure 1 Core competencies of health social work. Sources: Clinical Social Work Competencies (Council on Social Work Education, 2009) and Practice Standards Committee, 2005. Public Health Social Work Standards and Competencies. http://oce.sph.unc.edu/cetac/phswcompetencies_may05.pdf.

are rooted in the same theoretical base and grounded by the same set of social work professional ethics, values, and code of conduct. For instance, a public health social worker may assist a community development project responding to a collective health issue affecting all the members, especially the vulnerable (Practice Standards Committee, 2005: 12), and a medical social worker may conduct psycho-education with a patient's family to reduce possible discrimination against the patient's diseases such as HIV/AIDS. The underlying values for the different services are the same: promoting social and economic justice. Health social workers have to interpret and apply those theoretical foundations and ethics flexibly across different practical contexts, and, therefore, critical thinking and reflection is crucial during their practice. Professional supervision also serves as an on-going support for social workers, helping them to better understand, review, and reflect on their practice.

The two ovals on the top are core competencies, respectively, summarized for medical social work and public health social work. Their domain-specific professional knowledge and skills are listed. It is clear that their emphases are different (see **Figure 1**). Meanwhile, core components such as assessment, evaluations, creativity, research, advocacy, and policy practice are shared. Health social workers often advocate for access of services, clients' rights, and justice at multiple levels for the purpose of reducing health disparity (Council on Social Work Education, 2009: 4–7). In policy practice (Practice Standards Committee, 2005: 21–22; Council on Social Work Education, 2009: 8), health social workers actively:

- engage in policy practice regarding agency, regional, or national policy, law, and regulations;
- identify gaps, collect data relevant to particular policy, build coalitions, and plan for action; and
- inform legislators and administrators, and collaborate with others for effective policy actions at the organizational and societal level.

Challenges and Opportunities

Challenges in Health Social Work Practice

There has been increasing pressure on the justification of professional social worker positions. Naturally, a shift of focus flows from macrolevel social work such as community development to more tangible areas in direct services. Therefore, the productivity requirement for frontline social work duties has been raised drastically. Community-based social workers may have to prioritize their time allocated to advocacy as their major duty is specifically tied to the hourly 'fee-for-service,' for instance, assessment on whether an adult is eligible for certain benefits. While the waiting list is getting longer, other daily functions of these social workers can be overwhelming. It is difficult, if not impossible, to devote time for research, continuing education, and service improvement, which are vital for creating 'knowledge-in-practice' (D'Cruz, 2009: 69–71).

Another challenge is the demand for cost-efficiency and accountability. The call for 'pragmatic evaluation' for practice, promoted by the managerialist approach, lead to the use of simplistic performance indicators to guide practice (Payne, 2005: 219, 241). Priorities are given to productivity, data input, documentation, and funding applications, which may 'squeeze' the quality of direct client contact to the side. For

example, one of the major complaints from mental health social workers working with public medical reimbursement system in the US is their struggle on a weekly basis to meet the demanding paperwork submission.

There are debates and concerns on the use of existing scales and assessment protocols to measure risk and needs, make diagnosis, and determine priority and access to services. For example, despite the fact that DSM-IV-TR and ICD-10 are widely used in the US, some social workers find these mental health assessments disconnected with the clients' holistic bio-psycho-social wellness guided by social work professional values (Dziegielewski, 2004: 235). In addition, current social work assessment in health care settings is often under the pressure for moving clients through the system quickly through discharge planning, to save medical costs by reducing period of stay in hospital. Thus, health social workers will need to develop and utilize more comprehensive psychosocial measures to support intervention plans (Dziegielewski, 2004: 211).

Challenges in Health Policy

As social problems of health disparities, poverty, and ill-health are closely linked, health social workers will inevitably adopt grassroots mobilization and collective community actions to fight system injustice and global inequity. However, it is probably much easier to obtain funding for microsocial work compared to macropractices, such as advocacy for system changes. Under heavy workloads, clinical and medical social workers normally find it very difficult to engage in additional activities, such as policy practice.

Many of the industrializing countries are so poor that there are few affordable and accessible primary health clinics and hospitals services available to the population. Social workers, if any, may be hired only by local or international NGOs. Community leaders and grassroot workers can be trained by social workers to provide disaster relief, refugee camps, community support to reduce maternal and infant mortality, enhance access to clean water, promote self-help nutrition programs, healthy sexual behavior, immunization, and women's development projects. Unfortunately, funding for community health in these nations, especially war-affected areas, is often insufficient and unstable. Despite, the fact that there are programs that offer joint master degrees in social work and public health (MSW-MPA), the uptake is usually small with few employment opportunities.

Public health social workers will have to be creative and innovative so to engage the community in social development and poverty alleviation projects. It is essential for social work educators and researchers to generate knowledge in community health promotion, disease prevention, and especially to serve disadvantaged populations who are socially excluded and marginalized. They will have to develop competency models of working with international organizations, mass and social media, as well as to train students in systems change, legislative reform, social entrepreneurship, organization, and project management. There are youth and community social workers who actively participate in promoting a green awareness and lifestyle, as well as engaging themselves in the advocacy to preserve the environment. Such global challenges cannot be addressed by the social work profession alone, as multiple levels of intervention with the involvement of other professions and other sectors will be necessary to tackle such environmental issues (Gray et al., 2013: 12–16).

Challenges in Ethical Issues

Health social workers are often in the midst of ethical debates in their practices. Advancements in medicine and genetics bring along controversial issues in genetic engineering – preserving oocytes and sperms after the death of individuals, gender selection, organ cloning, and transplant. Ethical debates also arise concerning the provision of services and support during life donor organ transplant, adjuvant surgery (such as mastectomy, colectomy) after diagnosis of cancer-prone genes, surrogate motherhood in reproductive technologies, termination of pregnancies when fetus are diagnosed with higher risk of defects, serving persons with different sexual orientations (LGBT) on issues of marriage and child bearing, and serving in disciplinary forces such as prison or refugee camps on management of victims and/or perpetrators of war/violence/rape who are trapped in social discrimination and political oppression. The dilemma of pro-life versus free-will of woman to decide on abortion appears every time in the US presidential election debates. While medical doctors and nurses can refuse to be involved in abortion due to religious reasons, these moral, ethical, and spiritual issues are less commonly discussed or debated among health social workers.

In resolving ethical dilemmas and debates, compliance and adherence to high ethical standards and code of conduct as well as engagement in advocacy are essential for professional social work organizations. The Association of Oncology Social Workers actively engages its members into advocacy and provides them with toolboxes in lobbying political leaders in the fight for cancer in the US. International social work bodies, IASSW and IFSW, state ethical practice principles together. They explicitly encourage social workers around the world to debate and reflect on the dilemmas and to reflect on and make 'ethically informed decisions' in their specific situations.

Opportunities in Education and Knowledge Development

With the importance of health social work being increasing recognized internationally, related social work trainings are offered in many advanced education programs. Most of these programs generally provide specialized courses in medical social work and psychiatric social work. In industrialized countries such as the US, Canada, and Australia where hospital social work is more established, continuing education programs for social workers to be cognized as social work specialist in oncology, pediatrics, gerontology, nephrology, cardiology, palliative care, bereavement, and more, are available. While addressing the needs for cultural sensitive practices, most of these specializations are originated and organized under the Western Medicine framework.

Though conventional training has been based on Western Medicine framework, increasing attention points to the indigenous healing wisdom and practices of the east and south on health social work interventions. There is an increasing proportion of people using Complementary Alternative

Medicine in the treatment of pain, insomnia, diabetes, and autoimmune diseases internationally. Based on Eastern philosophical thoughts, Traditional Chinese Medicine, and meridian concepts, Chan and her colleagues established an integrative IBMS social work empowerment intervention in health care since the 1990s (Lee et al., 2009; Chan et al., 2012). Following years of practice and research, evidence for the IBMS model has been accumulating across various populations including cancer patients, women with health issues, and depressed populations (Lee et al., 2009; Chan et al., 2012). A number of randomized controlled studies have highlighted the effectiveness of the IBMS model on improving the well-being of participants (Chan et al., 2006; Hsiao et al., 2011; Liu et al., 2008; Yang et al., 2009). The team has also started to test the efficacy of traditional Chinese movement exercises, such as Qigong on persons with chronic fatigue syndrome and Taichi on persons with schizophrenia, and evidence of holistic improvement through psychosocial measures and physiological outcome markers was found (Ho et al., 2012; Ho et al., 2013). Given the increasing evidence, there is an urgent need for social work research and practice on how traditional healing wisdom from Asia, Africa, South America, and the Pacific Islands can be integrated and utilized by health social workers.

Conclusion

As a specialization in professional social work, health social work has been historically closely related to the environmental, sociopolitical, and economic context of the society. Health social work can roughly be divided into the medical stream and the public health stream. While medical social workers provide clinical services and support to patients, public health social workers work on global injustice to build a more socially inclusive and harmonious society. Contemporary changes on sociopolitical environment, medical technology, and poverty have led to new challenges in terms of practice, policy, and ethical issues. Continuing education programs, research for knowledge development, and social and policy advocacy are key in meeting the new challenges in promoting general well-being of the populations, as well as the health, harmony, and well-being of society.

Health Surveys

Abstract

Information on the health of a population can be obtained through a variety of data collection systems: health surveys represent one mechanism. Major topics to be covered include aspects of survey design, conceptualization and measurement of health status, determinants of health, summary measures of health, health care utilization, and health behaviors. The effect of recent technological advances on data collection methods are discussed as are the growing opportunities for data linkage and the future challenges of providing access to data while protecting confidentiality and privacy.

According to the most recent data available for the United States, 10.1% of the population are in fair or poor health; 7.8% of children under 18 years of age have no health insurance coverage; 68.5% of children 19–35 months old are up-to-date on immunizations; 19.3% of adults smoke cigarettes; and 31.9% are hypertensive based on measured blood pressure or use of blood pressure medication (National Center for Health Statistics, 2012). Such information is used by public health officials to plan, conduct, and evaluate programs; by elected officials to inform policies and legislation; and by researchers to expand knowledge about health and health care. Information on the health of a population can be obtained through a variety of data collection systems; health surveys represent one mechanism.

While health surveys are sponsored and carried out by many entities, core information is generally obtained through relatively large, multipurpose, government-sponsored data collection systems. These types of surveys will be the focus here, although most of the issues discussed pertain to all health surveys. Information from health surveys are used to profile the health of the population, to track demographic shifts and trends, and to monitor change in health and health care. In addition, the data are also used to investigate epidemiologic relationships between risk factors and health outcomes and to provide information for prevention, evaluation, research, planning, and policy.

The multidimensionality of health increases the complexity of health surveys and requires the use of different data collection methods. Of particular importance is how measures of health status are translated into data collection instruments. Measures of determinants of health, health care utilization, and health behaviors are also needed. Recent technological advances in data collection methods are changing how information is being obtained, including growing opportunities for data linkage, but these advances also present challenges for providing access to data while protecting confidentiality and privacy. As nations include general-purpose health surveys in their statistical systems, it is tempting to directly compare the results of these surveys; but cross-national cultural differences and variation in the nature of health care systems as well as survey designs, must be taken into account when making international comparisons.

Definition and Operationalization of Health

The World Health Organization's definition of health as a state of physical, mental, and social well-being and not merely the absence of disease or infirmity, provides the starting point for health surveys (WHO, 1948). However, because this definition is broad, complex, and multidimensional, it is difficult for any single survey to collect all the needed information. Depending on the specific objectives of a particular survey, there will be variation in the universes from which the samples are drawn and in the health and health-related information obtained. Since health is both a biologic and a social construct, health surveys must reflect this duality. In fact, these interrelationships between the biological and social aspects of health are often best approached through health surveys; and advances in technology have made it increasingly possible to incorporate direct measures of the biologic aspects of health into more traditional surveys.

General Design Issues

Health surveys can obtain information directly from individuals (the subject or an informant), can rely on administrative records, or use a combination of both approaches. A wide range of sampling methodologies, sampling frames, and data collection strategies are used, depending on survey objectives and the characteristics of the area in which the survey is done. Countries that have universal health care with centralized administrative systems can utilize designs that would be inappropriate in countries with less well-developed or decentralized health care systems. The simplest sampling scheme is a simple random sample of a population obtained from a complete and up-to-date list, such as the census of the population or a centralized health care system. In the case of surveys of persons, if such lists do not exist, area sampling can be used with clustering to reduce costs. In order to be able to report information on subpopulations of interest as defined by geography and/or demographic, socioeconomic, or health characteristics, designs often include oversampling of these groups. It is often necessary to incorporate screening into designs to achieve this objective. Information can be obtained either by mail, phone, in person interview, examination through the web, or by some combination of modes depending on the ability of the researchers to contact the population using these means. The latter three modes can also incorporate computer-assisted technologies, which enhance data quality and timeliness of data release. The rapid adoption of cell phones has affected phone surveys, generally by reducing

already-low response rates (Marsden and Wright, 2010). To reduce potential bias resulting from differences between the wireless-only and landline-only populations, many phone surveys have chosen to include wireless numbers in the sampling frame; however, response rates for wireless numbers are extremely low (Brick et al., 2006; Blumberg and Luke, 2012). The Internet is growing in popularity as a timely, low-cost data collection mode. However, web-based sampling frames present challenges in obtaining a representative sample. (Marsden and Wright, 2010).

In general, obtaining information directly from the survey subject provides more reliable and valid health data. However, this is not universally true but depends on the nature of the information sought and the characteristics of the subject (Moore, 1988). For example, while accurate information on risk behaviors among adolescents can probably only be obtained from the adolescent in a private environment, adolescents are not good reporters of health care utilization or household income. Even more problematic is the situation where a health condition does not permit a subject to respond for himself or herself. Since eliminating the subject from the survey would seriously bias the results, a proxy respondent is often used.

Although necessary, the use of proxy respondents does introduce a source of error into health surveys, particularly longitudinal surveys. Information on the relationship of the proxy to the subject as well as the conditions leading to the use of the proxy can reduce this error. In other cases, 'subject reporting' is fraught with a great deal of measurement error. For example, information on the characteristics of an insurance plan is usually better obtained from the insurer rather than the person holding the insurance. Finally, reliable assessment of specific types of morbidity, risk factors, and mortality requires direct measurement through physical examination or access to administrative records from health care providers.

Many health surveys limit their populations of interest. For example, it is common for health surveys to only include the noninstitutionalized population. The dramatic differences in the living conditions of the institutionalized and noninstitutionalized populations make it difficult to design survey methodologies that would apply in all situations. The military population is also often excluded from general health surveys. The scope of the universe needs to be clearly defined, especially if populations that differ in their health status – such as persons residing in nursing homes – are omitted.

When obtaining information directly from the population is inefficient or would result in either poor data quality or high costs or both, an alternative is to sample from existing records that were created for other purposes. Information on health care utilization for specific conditions is more easily obtained from hospital or health care provider records than from a population sample, given the relative rarity of the phenomena of interest. The vital statistics system can also be considered a survey of administrative/legal records for the purpose of describing the health of the population. Administrative systems, in addition to providing basic health information, are often used as sampling frames for population-based surveys. They are very attractive for this purpose as they eliminate the need to identify members of the population who have the characteristics of interest.

Health Status

Health status is a multidimensional concept, requiring multiple indicators and multiple methodologies for adequate measurement. Several different indicators of health status are usually included in health surveys, including single summarizing measures; questions relating to disease incidence and prevalence; and questions relating to functioning (physical, cognitive, emotional, and social) or disability (Stewart and Ware, 1992). Health status measures also vary depending on whether they are based on objective information obtained from standardized examinations or medical records or from information obtained from the individual or a proxy. To be most effective, individual health surveys should capture a variety of aspects of health status so as to provide a more comprehensive and complete assessment of health status than would be possible from any single strategy. Measures of health status should also be constructed to be useful in epidemiologic analyses of risk factors as well as for monitoring trends.

There is often interest in using a single question to measure health status in health surveys, as well as in surveys of other areas, such as employment, income, or education. The subject's self-assessment of his/her health status as excellent, very good, good, fair, or poor is a popular summary indicator of health status. This measure has been shown to be highly correlated with other measures of health status and is predictive of mortality and admission to long-term-care facilities (Idler and Angel, 1990). However, this measure can be problematic when used to monitor change over time. The means by which individuals evaluate various aspects of health have been shown to be affected by contextual parameters. Implicit in self-perceived health status is the individual's evaluation of his/her health status against some unstated standard. Societal norms act to define the standard but the norms and the standards change in response to a variety of conditions.

Medical Conditions

A variety of approaches can be used to measure disease incidence and prevalence including diagnosis by a health care provider; symptomatology (if an appropriate symptom battery exits); or medication use. Additional information of interest related to conditions includes date of onset, the use of health care services, and the impact of the condition on the individual's ability to function. Severity of condition is often inferred from the type of medications or health care services used or the nature of the impact of the condition on functional abilities. In examination surveys, diagnostic testing adds to the information available on the prevalence of conditions. Most important, direct physical exams allow for the measurement of previously undiagnosed conditions.

Major issues in the collection of 'condition data' are the number of conditions to be considered and whether the condition needed to be diagnosed by a health care provider. Condition checklists can be used to obtain information on a great number of conditions, but in most cases, only a minimal amount of information on any given condition is collected. In addition, long checklists are difficult to administer and result in reporting errors. However, the use of

comprehensive lists does allow for the ascertainment of comorbidities. An alternative is to obtain more detailed information on a select group of conditions. Criteria such as the prevalence of the condition or its potential impact on the individual and the health care system are used to select the target condition. Access to the health care system also affects whether a condition has been diagnosed and can be reported by a respondent. This affects reported prevalence rates and makes it difficult to investigate the social correlates of health status, since the definition itself incorporates a social dimension. The collection of information on symptoms takes on greater importance when investigating chronic conditions that may or may not have been diagnosed. Diagnostic examination or testing is necessary for some important conditions, which may be asymptomatic in their early or less-severe stages.

Self-reported information on self-perceived health status, disease symptomatology, physician diagnosis, and level of functioning is also obtained through interviews with participants; but the results of physical examination and of the blood- and other tests can be used to measure health status objectively. For example, information on diagnosed diabetes is obtained from the interview, and information on undiagnosed diabetes is obtained from blood tests. Information on functional limitations related to diabetes (e.g., vision and mobility problems) coupled with similar information available from the other components of a survey allows for a detailed characterization of an individual's health status. The information is also used for the investigation of risk factors for disease and for monitoring of functional outcomes. Since the 1960s, the use of examination surveys has grown worldwide, ranging from comprehensive examination surveys to the addition of at least some physical and biological measures to health-interview surveys (Tolonen et al., 2008b). Surveys differ in the extent of physical measurements and the medical and laboratory tests conducted and may or may not include nutritional assessment. In an effort to standardize protocols and information collected across countries, the European Union reviewed methods and developed recommendations for member countries (Tolonen et al., 2008a, 2008b). Examination surveys utilize various sites for collection of physical measurements and laboratory testing, including mobile clinics, health centers, and the participant's residence, which in turn affects the types of measurements and testing that can be done. One of the oldest and most comprehensive examination studies, the National Health and Nutrition Examination Survey, is conducted in the United States and combines health and nutrition interviews with physical examinations and laboratory tests administered by trained health professionals in a specially designed and equipped Mobile Examination Center (MEC) (http://www.cdc.gov/nchs/nhanes.htm). Canada also uses MECs for their Canadian Health Measures Survey (www.statcan.gc.ca). The United Kingdom's Health Survey for England (http://www.natcen.ac.uk/series/health-survey-for-england) conducts health interviews and, for those that agree, a nurse obtains body measurements and blood pressure in the participant's residence.

Information on conditions can also be obtained from the surveys of health care providers (hospitals, private physicians, hospital outpatient departments, emergency departments, ambulatory surgery centers, and long-term care). Sampling frames of providers must first be developed. Random samples of discharges, stays, or visits are then selected from the records of a random sample of providers. Information on conditions is routinely found in medical records in addition to other descriptive information concerning the patient and the encounter. Such survey designs are generally used to obtain information on health care utilization and the health care system, but the information available can also be used to study conditions that are associated with medical care.

Health care or health provider surveys offer independent assessment of the prevalence of disease by approaching the problem from the provider's side rather than the patient's side. Health care surveys are particularly important since they obtain information on rare conditions that would not be picked up in population-based surveys. Since data are obtained from existing patient records, they also allow for larger sample sizes than would be obtained from population-based surveys given the same resources. While information is collected on all conditions for which health care is obtained, the nature of the information available is limited to that which would routinely be obtained from records. In addition, the event (e.g., the discharge) rather than the person, is the unit of analysis. For example, while it is possible to estimate the number of hospital stays associated with hip fracture, it is not possible to estimate the number of persons with hip fracture, even if one could assume that all hip fractures were admitted to hospitals. An enhancement to health care surveys would be to contact patients after the health care encounter and obtain information from them about their health and health care prior to the encounter and after it.

'Cause of death' statistics obtained from a vital statistics system also provide essential information on medical conditions. While not error free, a great deal of effort is put forth to standardize the collection and coding of cause of death through international classification systems (http://www.who.int/classifications/icd/en/) as well as training for persons completing death certificates. The adoption of electronic death record systems will improve the quality of 'cause of death' reporting.

Functioning

An important component of health status concerns its functioning – sensory, physical, cognitive, emotional, and social. While 'conditions' relate more to the physiologic aspects of health, 'functioning' captures the pathways through which health conditions impact social participation. The International Classification of Functioning, Disability and Health (ICF) developed by the World Health Organization provides a framework for measuring health and disability at both individual and population levels (http://www.who.int/classifications/icf/en/). The ICF also contains a detailed classification system that can be used to code various aspects of functioning and disability.

Information on functional status can be ascertained through objective tests but is most often obtained through direct reporting by an individual or a proxy. Information on functional status encompasses a wide range of activities from the very basic, such as raising an arm, to the more complex, such as working and going to school. Obtaining information

on functioning is complicated by the fact that performance is affected not only by physiologic abilities but by the environment as well. A person's ability to walk may be impaired by a condition that leads to weakened muscles, but with the use of braces or a wheel chair along with appropriate accommodations in the physical environment (e.g., ramps), that individual is mobile and able to carry out appropriate social roles. For some purposes, information is needed on functional ability without the use of assistance of any type. In other cases, functioning ability as measured by usual performance is important. In any case, questions concerning how performance should be measured must be specific. A large number of question batteries have been developed to measure function (McDowell and Newell, 1996). Some use only a few questions, focus on the more complex social roles, and do not differentiate between aspects of functioning (physical, cognitive, emotional, or behavioral). Others are quite lengthy and obtain detailed information on a wide range of activities both with and without assistance.

Standard question sets for the measurement of functioning and disability have been developed for use on censuses and surveys by the Washington Group on Disability Statistics, a United Nations (UN) city group that was tasked by the UN Statistical Commission to address issues on noncomparability in disability statistics. The Group has developed and tested a set of six questions covering a core set of functional domains for use on censuses and an extended set of questions for surveys that addresses a wider range of domains and obtains more information for each domain. A set of questions for children is currently being tested. The ICF was used as the framework for developing the question sets and the adoption of these standard, tested questions will enhance the quality and comparability of disability statistics worldwide (Washington Group on Disability Statistics, 2009, 2011).

Many health surveys are limited to the noninstitutionalized population and therefore do not include those segments of the population in poorest health or with the highest level of functional limitations, such as those in long-term care settings. Special studies of these populations can be carried out and there should be some attempt to combine results from the noninstitutionalized and long-term care populations. Changes in the delivery of long-term care with the expansion of transitional establishments have made this an even more important issue for survey designers.

Determinants of Health

Health surveys generally include measures of risk factors, health behaviors, and nonhealth determinants or correlates of health, such as socioeconomic status. The range of measures that can be included is wide and varies by survey. Basic demographic and socioeconomic variables are usually included (i.e., age, race/ethnicity, education, income, urbanization, regionality). Tobacco use, alcohol use, diet, and physical exercise are common health behaviors. In order to identify causal relationships between determinants and outcomes, longitudinal designs are needed; however, cross-sectional surveys can be used to monitor changes in the prevalence of risk factors and other health behaviors. Changes in risk factors can be viewed as early signs of future trends in health status. Such factors can be considered leading health indicators. For example, observed declines in smoking levels signal future changes in lung cancer and other conditions caused by smoking. These leading health indicators can be important tools for planning and evaluating public health programs and policies.

Summary Measures of Health

There has been considerable interest in the development of summary measures of health in order to more easily characterize and monitor the health status of populations and for use in cost-benefit and cost-effectiveness analyses. There is also increasing interest in developing basic health status indicators comparable to the economic indicators currently in use. These indicators would be used to monitor the effects of public policy and to identify areas where interventions are needed. An overall health measure is very appealing in this context. Many health surveys include the information necessary to calculate the summary measures that have been developed. One such approach is to use a measure of morbidity or health status to transform life expectancy into 'healthy' life expectancy. Examples include parameters such as Disability Free Life Years, Healthy Life Expectancy, and Years of Healthy Life. Constructs such as these combine measures of different aspects of health into a single number using a conceptual model that views health as a continuum. The health states along the continuum are each assigned a number that represents the value that either society as a whole or the individual places on the particular health status. Various methods have been used to determine the values of the different health states. (Erickson et al., 1989).

Health Care Utilization

The use of the health care system is a major dimension of health. Information on utilization and related characteristics such as health insurance is collected from person-based surveys and through surveys of administrative records. In person-based surveys, respondents are asked to recall the number of contacts they have had with various health care providers and the nature of the provider and the contact. Information on the receipt of particular services, such as immunizations or mammography, is also obtained. This is often difficult for respondents. Research has shown that reporting of visits to the doctor drops off considerably when the recall period extends beyond 2 weeks (Edwards et al., 1996). To address this recall problem, some surveys ask respondents to keep detailed diaries of their medical care contacts. They obtain the names of the providers and then contact the providers (with the subject's permission) to verify the self-reported information (Monheit et al., 1999). Information on utilization can also be obtained from surveys of providers, and these usually provide more accurate information on the nature of the contact, including the reason for contact and the services provided. Surveys of providers can also yield valuable information on the structure of the health care system itself

and how the characteristics of the system affect access to care and the cost of care.

Longitudinal Designs

Most health surveys use a cross-sectional design which provides data for the calculation of population averages and is most appropriate for monitoring changes in health over time at the population level. A cross-sectional design is not appropriate for investigating causal patterns or for documenting transition probabilities from one health state to another where change at the individual level needs to be measured. A solution would be longitudinal studies which are expensive and more complicated to operate. One alternative is to transform cross-sectional studies into longitudinal studies by linking information from mortality, hospital, and other administrative records to the survey data. To do this, variables such as name, birth date, address, and other identification numbers are linked across unrelated datasets (Jutte et al., 2011). These data linkages allow researchers to examine factors such as health care utilization, patient outcomes, disease progression, and mortality. Population survey data are also linked to environmental exposures such as air monitoring data (http://www.cdc.gov/nchs/data_access/data_linkage_activities.htm). In Sweden and Finland, where all hospital discharges and deaths are registered in national databases, researchers have linked morbidity data to mortality data to study the incidence and progression of cardiovascular disease (Mähönen et al., 2000; Hammar et al., 2001).

Technological Advances

Advances in technology have affected the conduct of all surveys. Computer-assisted telephone and personal interviews have allowed for increasing levels of complexity in survey administration. Errors associated with keying and coding have been replaced by errors associated with programing; however, improvements in the development of survey tools continue. The use of these technologies has resulted in the need for longer lead times prior to implementing a study but has reduced the time from the end of data collection to the availability of results.

The increase in the use of electronic (as opposed to paper) files has greatly expanded the opportunities for linking data from various sources. Ecological or contextual information about the geographic area in which survey respondents live can now be linked to the survey data. This has the advantage of allowing researchers to address different levels of analysis. Survey data can also be augmented with administrative data from mortality files and from health care providers. In addition to reducing survey costs, this often leads to data of improved quality.

Methodological Research and Analytic Techniques

The quality of health survey data has been greatly increased by methodological research on survey techniques (Bradburn and Sudman, 1979; Fowler, 1995; Lessler and Kalsbeek, 1992). A major advancement has been the development and application of methods for questionnaire construction and evaluation (Sirken et al., 1999). Cognitive research laboratories have been established and can investigate how respondents perceive and answer questions. Another fruitful area of research involves study of the behavior of both interviewers and respondents within the social context of the interview situation (Cannel et al., 1977). A more structured approach to the errors found in health surveys will enhance data quality. The results of this research will lead to improved design that minimizes error but will also lead to ways to adjust for known errors in the analysis and interpretation of results (Jabine, 1987; Madans et al., 2011).

Advances have also been made in the development of appropriate analytic tools for use with health survey data. These include methods to account for such issues as survey nonresponse and complex survey design. As it becomes possible to collect data of increasing complexity, it will be necessary to develop the analytic approaches appropriate for the collection methods used (Korn and Graubard, 1999; Biemer et al., 1991; Groves and Couper, 1998; Rubin, 1987).

Privacy and Confidentiality

For ethical reasons and in order to obtain high response rates and valid information, most health surveys closely guard the information provided by respondents. In some cases, the requirement to protect confidentiality is legislatively mandated. This is particularly important for health surveys, given the personal nature of the information collected. Confidentiality can also be protected by not releasing data that could identify a respondent. Most survey sponsors subject files that are to be released for public use to rigorous disclosure review. The risk for inadvertent disclosure has increased in recent years, given the ability to easily download survey data and the availability of increasing amounts of information on the web which can be used to identify individuals in the survey data files. It is the potential for linking survey data to these external databases that increases the risk of disclosure, and the risk increases with the amount of information that is available.

The ability to link external data to survey responses presents an analytic breakthrough because the utility of survey data can be greatly increased through appropriate linkages; however, this ability also greatly increases the risk of disclosure especially when the linkages are done in an uncontrolled and inappropriate way. The increased sensitivity to issues of privacy in many countries, especially as related to health care, is affecting the manner in which confidential data are being protected. There has been a decrease in the amount of data that can be released as public use files. Other mechanisms are being developed so that access to data can be maximized while protecting confidentiality. The use of special use agreements, licensing, and research data centers are examples of these approaches (Journal of Official Statistics, 1998).

Hebb, Donald Olding (1904–1985)

Abstract

Hebb was very well grounded in the psychological theories of the early twentieth century by his graduate training at McGill, Chicago, and Harvard before his almost unique experience of measuring the mental capacities of human patients with surgical brain lesions. This impressed upon him the importance of the brain for determining behavior. He recognized that, although the proponents of the mainstream stimulus–response theories claimed to reject neural explanations, they in fact based their theories on a ridiculously simplified brain in which sensory input went directly to motor output. He therefore developed a behavior theory that involved a more realistic model of the brain and in doing so, brought about a profound change in the course taken by psychology.

Introduction

Donald Hebb was responsible in no small part for the great changes in the outlook of psychologists that took place in the 1950s. Few, if any, books have changed the course of psychology as radically as his major work, *The Organization of Behavior* (1949). The cognitive theory based on the association of neurons representing ideas that he advanced in that monograph was an important factor in the demise of neo-Pavlovian behaviorism, the attempt to explain behavior in terms of conditioned stimulus–response associations that was very influential up to that time. But more important, on the positive side, Hebb overcame the widespread aversion among psychologists to explanations of behavior in terms of brain activity. What was known about the brain at the time seemed irrelevant to the commonly espoused behavior models, so that attempts to introduce physiological interpretations were often regarded as waste of time and effort.

Mainstream behaviorists also rejected mental explanations of behavior, believing that thoughts and other mental processes were beyond the bounds of physical measurement, hence resorting to them might be regarded as vitalism. This forced them to ignore phenomena such as attention, expectancy, and ideas that Hebb regarded as essential to behavior theory. Hebb's mentor, Karl Lashley, postulated that concepts were represented in the cortex by patterns of neural activity that he called engrams; Hebb argued that if ideas can be represented by physical processes in the brain, they should be just as capable of forming associations with each other as were the behaviorist's stimuli and responses. Hebb's model incorporating association of ideas was more versatile than stimulus – response models, so it was enthusiastically adopted by the many psychologists who had found the established theories lacking in scope.

The Organization of Behavior presented the first theory of behavior based on the nervous system to attain widespread acceptance among psychologists. There is ample evidence that the consequent interest and participation of psychologists in brain research helped to fuel the vigorous growth of neuroscience that took off during the last half of the twentieth century.

Early Life and Education

Hebb, the eldest of four siblings, was born on 22 July 1904 in Chester, Nova Scotia. Both his parents were physicians. He was educated at home until he was 8 years old, by his mother, who used Montessori methods of teaching. He then attended the local school, which he found very boring.

Hebb's ambition as a young man was to become a novelist. He graduated from Dalhousie University (Halifax, Nova Scotia) in 1925 with a BA in English and Philosophy, though his father had urged him to specialize in science and mathematics, in which he obtained higher grades. While awaiting inspiration for the 'Great Canadian Novel,' he returned to his village school as a teacher. Some of the students remembered him as a former student and he was not a great success. Hebb recalls (Hebb, 1980a) that when the Provincial Inspector visited the school he attempted to cheer him up by telling him "I wasn't worth a damn in my first year either." By the time Hebb joined the teaching staff at McGill in 1947 he had become an excellent teacher, both of very large undergraduate classes and small graduate seminars.

Hebb's novel made little headway so, in search of wider experience, he spent the next summer as an itinerant farm worker in western Canada and then tried, unsuccessfully, to get a job as a deckhand in Vancouver.

In 1927 Hebb was back East, teaching in a Montreal high school. As a would-be novelist he had become interested in Sigmund Freud's ideas and applied to McGill University to study psychology part time. Professor Tait, the chairman of the psychology department at the time, was also from Nova Scotia and had known Hebb's mother in college, so he took it for granted that Hebb had to be intelligent. He was admitted to McGill in 1929 as a part-time graduate student in psychology. At the same time, Hebb was also appointed Principal of an elementary school in a working-class suburb of Montreal and, with assistance from members of the McGill psychology department, enthusiastically set about instituting and testing novel teaching methods intended to make learning more attractive to students (perhaps based on fond memories of his Montessori experience).

In 1930 Hebb was bedridden for a year with a tubercular hip, during which time he read Pavlov, Sherrington, and Ariëns Kappers (on neurobiotaxis) and demonstrated his innate empiricism by conceiving a theory of how spinal reflexes might be learned *in utero*. This formed the basis of an MA thesis titled *Conditioned and Unconditioned Reflexes and Inhibition*; Hebb later described it as nonsense (Hebb, 1980a). About 60 years later, I could not find the thesis in the McGill library and it was presumed to be lost. The idea that spinal reflexes are learned may well be nonsense, but as Richard Brown, who eventually unearthed the thesis, points out (Brown and Milner, 2002, 2003), the neural mechanism Hebb proposed to bring it about was not. It later formed the basis for the learning synapse that became known as the Hebb Synapse.

In 1932 Hebb began doctoral research, still part-time, at McGill. The experiments, which involved Pavlovian conditioning of dogs, were supervised by Leonid Andreyev, a former student of Pavlov. Hebb was not impressed either by the technique or by its interpretation, and when his first wife was killed in a motor accident, he abandoned the part-time research. Hebb enjoyed teaching and administration and was tempted to make a career of being a Headmaster. His enthusiasm waned however when the Quebec educational authorities clamped down on his more radical teaching innovations and he finally chose to continue his psychological studies.

In 1934, Hebb was accepted at Yale to work for a graduate degree with Robert Yerkes, a well-known psychologist who studied intelligence in humans and other primates, but he was dissuaded from accepting this arrangement by Boris Babkin. Babkin was another former student of Pavlov who had moved to the McGill Department of Physiology, and he was one of the examiners of Hebb's Master's thesis. He urged Hebb to go to the University of Chicago and work with Karl Lashley, whose book, published a few years earlier (Lashley, 1929), had established him as the preeminent physiological psychologist of the period, Hebb followed Babkin's advice.

This choice was significant as it is very unlikely that *The Organization of Behavior* would ever have been written had Hebb gone to Yale where Clark Hull, the leading exponent of a neo-Pavlovian behaviorist school, held sway. Yerkes was mainly interested in intelligence testing in humans and other primates. He was of the opinion that foreigners were less intelligent than American citizens because they obtained lower scores in his tests (which incidentally had many culturally loaded questions), a degree of chauvinism that might have been a factor in Babkin's advice.

Hebb spent a year in Chicago where, in addition to his close association with Lashley, he attended lectures on Gestalt psychology by Wolfgang Köhler, on statistics by Thurstone, and on physiology by Nathanial Kleitman the authority on sleep, whose lectures, according to Hebb, were appropriately soporific. Lashley then accepted the offer of a professorship at Harvard and arranged for Hebb to go with him to continue his graduate research as a Harvard scholar. The transfer interrupted Hebb's research on the effect of cortical lesions on spatial learning in the rat. So Lashley suggested that he study the vision of dark-reared adult rats to ascertain the effects of being reared in darkness – an experiment that could be completed in the time available.

Hebb, the empiricist, might have been expected to believe that vision would be impaired in dark- reared rats. Instead, perhaps influenced by Lashley's predilections, he found that dark-reared groups of rats could learn to discriminate brightness and shape just as well as normally reared groups. However, he managed to ignore the fact that it took the dark-reared rats six times as many trials as the control rats to acquire the skill. His thesis was accepted and he was awarded a Harvard PhD in 1936.

Montreal Neurological Institute

In the 1930s, physiological psychology was not taken seriously by most psychologists and jobs were scarce. Lashley gave Hebb a postdoctoral year of research so that he could complete the work on spatial learning that he had started in Chicago. The next year, 1938, Boris Babkin again played a role in shaping Hebb's career, though on this occasion an indirect one. Hebb's sister Catherine was doing research at McGill for her PhD in physiology with Babkin, when she heard that Wilder Penfield, the neurosurgeon who had recently founded the Montreal Neurological Institute (Neuro), was looking for somebody to study mental changes resulting from brain operations in epileptic patients. She relayed this information to her brother who applied for the job and was offered a two-year Fellowship. Penfield's operations were mostly frontal and temporal lobectomies performed to remove epileptic scar tissue.

Hebb did not rely entirely on standard tests; he devised several ingenious tests for special purposes including a series of ill-drawn scenes containing incongruous elements, which the patient was asked to point out. Hebb found a patient with a right temporal lobe removal who showed a deficit on these visual tests; an early suggestion that the temporal lobe might be involved in vision. His most surprising finding was that a large removal of the frontal cortex had little effect on intelligence as measured by a standard Stanford–Binet test (Hebb and Penfield, 1940). The frontal cortex, being relatively larger in humans than in other animals, had been thought to be very important for intelligence. At first Hebb was disappointed at his finding, but then he realized he had uncovered an important phenomenon that required explanation. Much of Hebb's subsequent research was based on his investigation of this problem.

Hebb maintained his association with Penfield and other members of the Neuro staff. When he returned to McGill in 1947 he sent his graduate students to seminars at the Neuro given by Herbert Jasper in neurophysiology and by Francis McNaughton in neuroanatomy. Hebb also obtained permission from Penfield to install one of his graduate students at the Neuro, in order to study patients before and after surgery. This had a far-reaching effect on our knowledge of the effects of brain lesions in human patients, mainly because one of the first students Hebb sent to occupy this position was Brenda Milner. She is still there, more than 60 years later.

Primate Research with Lashley

After his Neuro Fellowship, Hebb obtained a post as Lecturer at Queen's University (Kingston, Ontario). There, in addition to

teaching four courses he, with his student K. Williams, devised a rat-maze (the Hebb–Williams maze) with movable partitions so that he could continue his brain-lesion research using rats. In 1942 Lashley offered him a 5 year Fellowship to study the effects of brain lesions in chimpanzees at the Yerkes Laboratories of Primate Biology in Orange Park, Florida, where Lashley had taken over after Yerkes retired. Hebb would have preferred to study the effect of suppressing learning in puppies to test his frontal-lobe theory, but his heavy teaching load at Queens made that difficult and so he settled for the chimpanzees.

The Orange Park project was to study the effects of brain lesions on intelligence and emotion in chimpanzees. Lashley was to work on intelligence tests and Hebb on tests of emotion. Lashley was surprised to discover that it was more difficult to measure learning in chimpanzees than in rats, with the result that no brain lesions were made before 1947 when Hebb's Fellowship ended. Hebb did not waste his time however; he had the opportunity to observe the personalities of a group of 30 chimpanzees and recognized many of the foibles to be found among a random group of people. In the process he assembled a good stock of chimpanzee stories that contributed to the popularity of subsequent lectures. More important, with the intellectually stimulating group of psychologists working with Lashley in Orange Park he also found incentives and time to write a great deal of his most influential publication, *The Organization of Behavior*.

McGill Once More

During the 1939–45 war, the McGill psychology department had dwindled to one part-time child psychologist, so in 1946 Prof. Robert McLeod was appointed Chairman with the mandate to rebuild the department. Hebb's fellowship at Orange Park ended in 1947, so he was an obvious candidate for the rebuilding team. He moved to McGill, bringing the manuscript of his book with him. He taught a graduate seminar and distributed copies of the chapters to the students for discussion. In those days, with a departmental teaching staff of only four or five, graduate seminars were held in the evenings. The students in Hebb's first seminar included Mortimer Mishkin, Bernard Hymovitch, Donald Forgays, Lila Ghent (Brain), Herbert Lansdell, Woodburn Heron, and Brenda Milner. Brenda was a graduate of Cambridge University who had a full time job teaching psychology, in French, at the Université de Montréal. She was interested in McLeod's phenomenological approach, and the previous year she had obtained permission to attend his evening graduate seminars at McGill. The next year, when Hebb gave his 'first-year' seminars, she also went to those.

Brenda was in Montreal because I had been sent from England during the war as a member of a group of scientists to work on nuclear energy, and she had come with me. Just before the end of the war, I was transferred from Montreal to Chalk River, a sparsely populated site in Ontario where the nuclear reactor was to be built. Brenda wrote to me very excitedly about Hebb's seminars and sent me copies of chapters that Hebb had handed out. Here was someone trying to figure out how neural circuits could explain behavior.

My speciality was electronic circuitry and in 1947 I was one of the multitude trying to decide on a peacetime career. I had many options but for several reasons I decided to stay in Canada and go back to school. I knew some of the McGill physicists, as they sometimes visited Chalk River. Prof. John Foster was building a cyclotron at McGill and I could have had the job of designing an ion source for it. Reading Hebb's chapters convinced me that I would enjoy studying with him more than with the physicists, so the next time I came to Montreal I made an appointment to talk to him about it.

I do not remember whether I knew it at the time, but when I met Hebb he had just been appointed chairman of the psychology department, as McLeod was moving to Cornell. I was duly impressed by Hebb and my interview with him went well. I discovered years later, when I read his autobiography, that he gave me more or less the same treatment he had received when he was in a similar situation 20 years earlier. He sent me away for a year to learn some psychology with the promise of admission to graduate school if I qualified.

The next year I experienced the famous Hebb Seminar first-hand. My first assignment was an article in the Journal of Neurophysiology by Lorente de Nó, a difficult writer, about the feedback loops in the cerebral cortex.

Having made a highly successful foray into the world of behavioral neuroscience (physiological psychology as it was then called), Hebb returned to teaching and administration with enthusiastic vigor. He taught the introductory course to overflow classes for 27 years, and wrote three editions of a highly respected introductory textbook. He also conducted a seminar for all incoming psychology graduate students (including clinical), instilling a thorough understanding of a range of theoretical issues and availing himself of the opportunity to coach the participants in the presentation of succinct and closely timed talks (his stopwatch and tapping pencil were famous far and wide, as were many of the seminars' graduates).

To test some predictions of his theory, he supervised research on the effects of early environment on adult behavior in rats and dogs, and the effects of sensory deprivation on human thought processes. He discovered that well-paid volunteers, subjected to extreme sensory deprivation, could not stand it for more than a few days (Heron, 1957). Hebb was unusual in that, despite being the principal investigator and final editor of ensuing publications of the work he supervised, he did not put his name on it unless he had collected some of the data himself. The deprivation experiments caused trouble later when, as discussed by Brown (2007), Hebb was accused of providing government agencies with a method of torture.

Hebb's Contributions to Psychological Theory

During his years as a graduate student, Hebb had learned the hard way what was wrong with contemporary psychology. At McGill, as is evident from the topic of his Masters thesis, he flirted with the extreme empiricism then rampant in North American psychology. Influenced by Boris Babkin and Leonid Andreyev, former students of Pavlov, he passed through a Pavlovian phase. When he moved to Chicago he entered the

Gestalt enclave of Wolfgang Köhler and Karl Lashley; and at Harvard he encountered the historian, Edwin Boring, who taught him what Psychology had been like before Behaviorism. Sooner or later, for reasons that are cogently presented in the first few chapters of *The Organization of Behavior* (Hebb, 1949), Hebb found flaws in all the established schools of psychology.

Because of his research on cortical lesions and his neural theories, Hebb is usually labeled a physiological psychologist, but his interests were really much broader. *The Organization of Behavior* was an important catalyst, aiding the revival of cognitive psychology, and although he was a zealous proponent of the idea that the brain is the organ of mind, Hebb's interest in neurophysiology took second place to his interest in thinking and other aspects of behavior. In his hands, neurologizing was a tool to restore respectability to the study of mental processes.

As a psychologist, Hebb was frustrated by the behaviorists' refusal to acknowledge such important processes as attention, expectancy, and thought, lest they should be accused of vitalism; hence his eagerness to show that those mental processes could be performed by a material brain.

Hebb based his neural model as far as possible on established physiological principles but neuroscience was on the brink of a revolution, and many of those principles were soon to be revised. For example, in 1951 Eccles, whose strenuous defense of the electrical theory of synaptic transmission Hebb had accepted, observed excitatory and inhibitory chemical synapses and recanted (Eccles, 1953). In addition, the behavioral importance of subcortical structures such as the reticular arousal system, the amygdala and the hippocampus became clearer; and improved staining techniques revealed a much more complex visual system than was known to Hebb when he was writing *The Organization of Behavior*. The fact that these revelations had almost no effect on the impact of Hebb's book shows to what extent the psychological implications of his neurologizing outweighed the underlying physiology. By proposing a material basis for concepts, Hebb demolished barriers to the study of cognitive processes that the behaviorists had erected a generation earlier.

In his Presidential address to the Experimental Psychology Division of the American Psychological Association in 1954, Hebb (1955) introduced the reticular activating system into his model to extend his explanation of emotion; but apart from that he did little to revise the theory in the light of new neuroscientific data. In spite of this, Hebb made a valuable contribution to neuroscience. As pointed out earlier, many psychologists, introduced to the nervous system by Hebb's theorizing, contributed useful behavioral techniques and ideas to investigations of neural processes.

Hebb's most famous personal contribution to neuroscience was not based on neurophysiological research; it was inferred from behavior. Most physiologists thought that learning synapses were strengthened by use, but Hebb, along with other psychologists, recognized that association involved at least two active paths. Thus he postulated that learning changes at synapses require simultaneous firing of both presynaptic and postsynaptic neurons. As pointed out by Brown, synapses with properties similar to those postulated were subsequently identified experimentally and were given the name 'Hebb synapses.'

Hebb held strong views about the 'nature–nurture' question. After his early gyrations, he adopted the unassailable position that both inheritance and experience are totally necessary for intelligent behavior, using the analogy of area (the product of length and breadth). Of course, one may still be interested in whether an area is square, long and narrow, or short and fat. In spite of Hebb's bipartisanship, his concept of the development of vision was long in the 'nurture' dimension; in fact, Hebb's visual cortex bore a strong resemblance to Locke's *tabula rasa*. Thus, Hebb assumed that neurons are randomly connected in the newborn visual cortex. With experience, synapses are strengthened between neurons activated simultaneously by sensory input, producing groups of connected neurons (*cell assemblies*) that then represent the input. Hebb further postulated that a complex figure elicits a series of eye movements, thereby activating a succession of associated cell assemblies that Hebb called a *phase sequence*.

Anatomical diagrams of the cortex suggested to Hebb that cell assemblies consist of networks of closed loops. This led him to speculate that once a cell assembly is activated, impulses continue to circulate around the loops for some time (reverberation), constituting short-term memory. In this way Hebb explained the persistence of an idea or mental image in the absence of the corresponding object. Today, short-term memory may be explained more plausibly by persistent chemical traces, but Hebb never abandoned his reverberation theory, which dominated the thinking of many neural-model builders in the latter part of the last century.

According to Hebb, the impulses reverberating around the cortical loops of an activated cell assembly produce synaptic changes that bind the neurons together more permanently. This explains long-term memory. Ideas arouse other ideas by association, thus cell assemblies must acquire associations with each other whenever they are active at about the same time. Hebb never satisfactorily explained how, after linking in this way, they avoid merging to become bigger cell assemblies.

The capacity to explain intention, attention, and other mental processes was an important goal of Hebb's theorizing but one that, in *The Organization of Behavior*, he was content to achieve in principle rather than by rigorous neural modeling. Short-term expectancy and attention were explained in terms of the phase sequence getting ahead of the sensory input. Thus a previously experienced sequence of stimuli sets up a central process that facilitates cell assemblies in advance of the sensory input they represent. Hebb postulated higher-order central processes that facilitate more extended sequences. In much of his writing Hebb treats the cell assembly as equivalent to an idea; its neural basis is tailored to fit behavioral observation.

In later years Hebb received many honors; he was President of both the Canadian (1952) and the American (1960) Psychological Associations. He was elected a Fellow of the Royal Society of London (1966), a Foreign Associate of the National Academy of Sciences (USA), and an Honorary Member of the American Academy of Arts and Sciences. He was elected posthumously to the Canadian Medical Hall of Fame. In1970 he was appointed Chancellor of McGill University. In 1974 Hebb retired to his family home in Chester Basin and became active in the psychology department of his *alma mater*,

Dalhousie University, where he was appointed Honorary Professor.

He published his last monograph, *Essay on Mind* (1980a). This is really a multitude of short essays, for the most part defending, though not dogmatically, his conviction that the mind is a biological function. Hebb, as usual, deploys his arguments with enviable and devastating reasonableness.

Summary

The Organization of Behavior is now a classic. Many psychologists regard it as the herald of the era of cognitive research that blossomed in the 1950s. Hebb's notion of the neural representation of concepts and their associations with each other is still common currency among psychologists, even those who prefer to ignore the brain; but devotees of neural networks and neurophysiologists studying sensory systems are those who most often refer explicitly to his theory.

After Hebb left Lashley's 'think-tank' in Florida and took up his duties as chairman of the McGill Psychology Department, most of his energies turned to building and running a strong department, with emphasis on teaching. Although Hebb took every opportunity to promote neurologizing in psychology, he showed little further inclination to keep pace with the rapid advances in neuroscience or to make any major changes to his neural theory. He was well aware that changes were required but he was content with the knowledge that his book had turned psychological theory toward the brain.

Apart from his own characteristically stylish and witty account (Hebb, 1980b), there have been several more recent commentaries that complement this entry for those who wish to learn more about Hebb's life and work. These include nine essays in his honor, written by former students and edited by Jusczyk and Klein (1980) and a delightful chapter by Stephen Glickman (1996), which admirably portrays the man and his achievements. Fentress (1999) and Klein (1999) edited a special issue of the *Canadian Journal of Experimental Psychology* that contains a further collection of papers on Hebb and on research inspired by his ideas. Orbach, a student of both Hebb and Lashley, published a book (1998) in which the contributions of his two mentors are discussed and compared.

In 2002 *The Organization of Behavior* was out of print and difficult to find, so Richard Brown had it reprinted. A foreword to this recent edition by Brown and Milner contains more information about Hebb. Lists of his publications and biographical obituaries are also included. Brown and Milner (2003) also published an article, *The legacy of Donald O. Hebb, more than the Hebb Synapse*. Other recent biographies of Hebb include Brown (2007) and Glickman and Brown (2008).

Abstract

G.W.F. Hegel (1770–1831) was one of the last great philosophers, who developed a system of all philosophical sciences: Logic, Philosophy of Nature, and Philosophy of Spirit. This article gives an outline about his life, philosophy, and influence on the social sciences. Hegel was born in Stuttgart (Germany), educated at the University at Tübingen, and worked as a private tutor in patrician families in Bern and Frankfurt. He began his academic career as an Associate Professor in Jena, was then the editor of a daily newspaper of Bamberg, and then principal of a secondary school in Nuremberg for 8 years. He then taught as a regular professor at the University of Heidelberg (1816) and at the University of Berlin (1818–31). His main works are *Phenomenology of Spirit* (1807), *Science of Logic* (1812–16), *Encyclopedia of the Philosophical Sciences in Outline* (1817, 1827, and 1831), and *Elements on the Philosophy of Right* (1821). In the development of the social sciences, Hegel's philosophy influenced not only Karl Marx, but also, what is less known, Lorenz von Stein, the St Louis Hegelians, Wilhelm Wundt, G.H. Mead, and Juergen Habermas.

Biographical Data

Hegel, Georg Wilhelm Friedrich the philosopher was born on 27 August 1770, in Stuttgart (Germany), and died on 14 November 1831, in Berlin. In 1788, Hegel, son of a medium-grade civil servant, entered the Protestant Seminary in Tübingen, where he won the friendship of his roommates Hoelderlin and Schelling. He held a ducal scholarship for studying Theology and Philosophy at the University of Tübingen. After graduating in 1793, he earned a living as a private tutor in patrician families, first in Bern, Switzerland (1793–96), and then in Frankfurt (1797–1800), where he regularly met Hoelderlin. At the beginning of 1801, Hegel joined Schelling in Jena and qualified for lecturing with his habilitation thesis *On the Orbits of the Planets*. While at Jena (1801–06), Hegel published his *The Difference Between Fichte's and Schelling's System of Philosophy* (1801). In the years 1802 and 1803, his essays *The Relationship of Skepticism to Philosophy, Faith and Knowledge*, and *On the Scientific Ways of Dealing with Natural Law* came out in the *Critical Journal of Philosophy*, which Schelling copublished with Hegel. The major work of this period was, however, the *Phenomenology of Spirit (PS)* (1807), which was intended to be the first part of Hegel's system of philosophical sciences.

After the Battle of Jena, Hegel, having no income, took over as editor of a newspaper in Bamberg in 1807 and 1 year later, he became the principal of a secondary school in Nuremberg. There, Hegel married Marie von Tucher with whom he had two sons. During the Nuremberg period, Hegel published his *Science of Logic* in three volumes (1812, 1813, and 1816), the first of which, the *Doctrine of Being*, reappeared in heavily revised edition in 1832. In 1816, Hegel was finally granted the privilege of earning a secured income as a full professor in Heidelberg. In 1818, owing to the personal intervention of Minister Altenstein, he became Fichte's successor in Berlin.

From 1816 on, Hegel published – apart from several minor writings – the *Encyclopedia of Philosophical Science* (1817 in Heidelberg, and in two greatly enlarged editions 1827 and 1830) as well as *Elements on the Philosophy of Right (PR)* (1821). His lectures on Esthetics, the History of Philosophy, and the Philosophy of History and Religion were attended not only by students but also by members of the Berlin society hungry for education. Until the mid-1940s, philosophy in Germany could not be exercised without taking a position on Hegel's philosophy. Moreover, his philosophy influenced the formation of those special sciences, which Dilthey later called '*Geisteswissenschaften*.' Soon after Hegel's unexpected death, his school split into different wings as a consequence of philosophical disputes on religion. In 1837, David Friedrich Strauss classified this splitting into the left (e.g., Karl Marx), the right (e.g., Friedrich Wilhelm Hinrichs), and the central (e.g., Karl Rosenkranz) (*see* Jaeschke, 2010; Pinkard, 2001).

Aspects of His Philosophy

Interests of the Young Hegel

The young Hegel studied the ancient authors, the literature of the Enlightenment, and above all Kant's critical philosophy, Rousseau's works on cultural criticism and theory of politics, as well as the dispute on Spinoza, which had been initiated by F.H. Jacobi. Furthermore, he enthusiastically paid close attention to the course of the French Revolution. At that time, he mainly worked on three questions. Firstly, how must a religious education of a people be conceived for it to strengthen the motivation for ethical and political action? This question had strongly suggested itself after Rousseau had failed to come to a convincing result concerning the question: which type of religion can be legitimated from the political point of view of a rational community? In his works on religion and ethics, Kant had then shown that a conflict is avoidable between religious and ethical duties on the one hand and religious and political duties on the other. Therefore, what mattered was to translate Kant's idea of such a union of all those duties into an educational program. Hegel, Hoelderlin, and Schelling devoted themselves to finding a corresponding way of life, which they called 'invisible church.'

Related to these interests is the second, historical question: what explains the fact that Christian faith developed into a 'positive,' authoritarian religion, which became a tool for

despotism to misuse? It was the strategic reaction of the established scientific community to the French Revolution and Kant's philosophy that gave rise to the third question; in the mid-1990s, the theological Orthodoxy of Tübingen began to misuse Kantian philosophy in an attempt to justify antiliberal church dogmas in a new manner. This led to the third question: how can Kant's critical philosophy be protected argumentatively from such a dogmatic misuse? From Hegel's penetrating critique, first of Kant's doctrine of postulates in the *Critique of Practical Reason*, emerged stepwise a system of philosophy whose position may be called 'speculative idealism.' But it did not replace his original interests; it was designed to answer them.

Phenomenology of Spirit

The PS exhibits the 'path of despair,' which 'natural consciousness' has to go in order to try to justify its knowledge claims under the conditions set forth by the contrast constitutive of itself: its own subjectivity – made into a first principle – in opposition to the objectivity not reducible to it. On the way, it becomes clear that the knowledge intended by various shapes of natural consciousness does not satisfy its own, immanent truth criteria. For example, the first shape of natural consciousness, called sense certainty, experiences its inability to refer immediately, i.e., without concepts, to supposedly *ontic* independent singulars by means of indexicals alone. This self-examination is the first step of the procedure. In a second step, '*we*,' who contemplate consciousness phenomenologically, have to identify this negative result – taken positively – with a new shape of consciousness. Out of the perspective of consciousness its process of self-examination will terminate only if it has produced a knowledge claim that fulfills its own truth criteria. Hegel calls the ultimate shape 'absolute knowing,' which is detached (Latin *ab-solvere*) from the contrast of subjectivity and objectivity constitutive of consciousness as such, so that it is not longer a shape of consciousness. Therefore, it presents the decisive step of the 'self-consummating skepticism' (Section 78) the PS exhibits – which may be summarized with Socrates' "I (a conscious experiencer) know that I know nothing."

Apart from the much discussed chapter 'Mastery and Servitude' – which exhibits how two people self-consciously struggling for recognition end up in the unstable – for recognitionless – shape of intersubjectivity of mastery and servitude – the chapters on practical reason, spirit, and religion of the PS should be of some interest to the social scientist. The chapter on Reason exhibits that any effort of self-actualization – i.e., gaining pleasure, making inner laws universally valid, and spreading virtue – must necessarily fail. Even a self-conscious practical reason cannot reach its goal of self-actualization if it merely tries to advance the concealed good of the world instead of rearranging the world in the first place.

The chapter on Spirit contains the doctrine of the basic convictions of a society concerning the purpose of society or its central elements. The internal problems of occidental societies – exhibited in their historical order – transformed them into one another, so that – in them – the Spirit reached new basic convictions about itself. The relevant problems, however, are not those that an objective observer of a later stage in history may discover, but those that the members of the societies in question could experience themselves as contemporaries.

In the chapter on *Religion*, Hegel carries out a similar analysis for the religions in history. As Max Weber after him, Hegel believed that the religions above all – *qua* their internally developed convictions – promoted a process of rationalization in world history, a process that Hegel comprehended as an advance in the consciousness of freedom. For him, Christianity was the religion that first gave effect to the principle of subjectivity and thereby pushed through the consciousness that *all* men as men are free. At the end of the PS, it is supposedly possible to expose a concept of cognition based on the historical experiences that natural consciousness has made in the course of history of occidental societies and religions. This concept, which Hegel called 'absolute knowledge,' has the process of these experiences as its contents and the type of rules concerning the transformation of the shapes of consciousness as its form. It is the purpose of this knowledge to promote humanity, whose existence 'lies only in the commonality of consciousness' brought about by the process of driving men forward 'to agreement with one another' (*see* PS, Section 69).

The knowledge arrived at in the PS, however, so far only concerns the historical genesis of the present as an epoch that still has to bring about humanity. In order to satisfy this demand, knowledge of what emphatically is has to be acquired, too (Preface to the PR). Since the PS has shown that certain fundamental concepts are the central constituents of each shape of consciousness, Hegel conceives of a doctrine of such 'determinations of thinking' in his *Science of Logic (SL)*: it has to examine whether these determinations are true for themselves.

Science of Logic

To logically unfold the socratic result of the PS is what Hegel declared to be the only 'proper metaphysics.' It is its task to develop an adequate concept of philosophical cognition and thereby of itself ('absolute Idea'). To fulfill this task, it primarily criticizes the aims at knowledge of pre-Kantian metaphysics and Kant's transcendental philosophy. In the SL, which is this metaphysics, the traditional concepts of Metaphysics and Logic incapable of defining a concept of the Absolute are improved in an iterated process: abstract understanding begins with trying to determine the traditional concepts in a way that makes them as distinct as possible from other concepts and hence suitable to define the Absolute. In a second step, dialectical reasoning demonstrates that no concept, however well determined by understanding, can be distinguished even from its opposite, and demands to skeptically suspend any judgment in the face of this negative result. But then, speculative reason identifies this negative result with a new term of the history of philosophy, which the understanding tries to determine again. Since the results of the first two steps are included in the new concept, the concepts of the SL become richer in content in the process. Once dialectical reason cannot even find an opposite concept anymore, the process reaches its end. Hegel calls this ultimate concept 'absolute Idea,' which is at the same time the concept of the philosophical cognition carried out in the SL (Fulda, 2003).

In the final step, this concept is arrived at by overcoming the dualism of our theoretical epistemic attitudes ('Idea of Truth')

and our practical ones ('Idea of the Good'). In these attitudes of finite cognition – paradigmatically conceived of by Kant as theoretical and practical reason – we regard the world not only as being a well-structured touchstone of our knowledge but also as insignificant and worthless in the face of the Good, which lies purportedly only in the will of the perceiver. The concept of the absolute idea is intended to free us from those conflicting references to the world. But in order not to give rise to a new conflict between the finite knowledge (prescientific and of the special sciences) and philosophical cognition, Hegel requires translation rules mediating between both types of attitudes and obliged philosophical cognition of the Real to demonstrate the correspondence of its results to 'empirical appearances' (Wildenauer, 2004). According to Hegel, a Philosophy of the Real depends therefore on integrating new expressions from other sciences to provide for a denotation of the philosophically developed concepts. To that extent, recognizing the Real is underdetermined by the SL, and a Philosophy of the Real as well as Logic itself depends on the developing status quo of the sciences.

Philosophy of the Real

The *Encyclopedia of the Philosophical Science in Outline* was meant to instruct the students who attended Hegel's lectures, and therefore only contains the rudiments and basic concepts of all philosophical sciences. The logic outlined above makes up the first part of the encyclopedia, the second and third parts being the Philosophy of Nature and Spirit. It is primarily through these two parts that we have access to Hegel's Philosophy of the Real.

Philosophy of Nature

In his Philosophy of Nature, Hegel tries to answer the question of how we can overcome the duality of our theoretical and practical interests concerning Nature and thereby satisfy our needs without turning Nature – and thereby aspects of ourselves – into the Other per se, which would merely become controlled by technology. This philosophy looks for a third way between the modern objectification and quantification of phenomena in the natural sciences on the one hand and a romantic subjectification of Nature on the other. In doing so it does not, however, regard itself as competing with the natural sciences, but rather tries – on the basis of the results of scientific research – to conceive of Nature as an idea in which we can finally recognize ourselves.

Philosophy of Spirit

In so far as Hegel gains his concept of Spirit from his doctrine of living natural beings, which contrasts the sphere of Spirit from that of Nature, he tries to overcome Descartes' dualism between *res cogitans* and *res extensa* in his whole Philosophy of Spirit, without, however, reducing the phenomena of one sphere to those of the other.

In particular, Hegel teaches in his *Doctrine of the Subjective Spirit* how the subjective spirit of individuals rises step by step from its embodiment (Anthropology) and its object-boundedness (Phenomenology) toward higher cognitive and voluntative competencies, which culminate in the knowledge of and will to its own freedom (Psychology). In the first part, the *Anthropology*, the phenomena to be comprehended are, e.g., dreaming, habits, aging, gestures, and mental disorders, while the *Phenomenology* treats the different levels of consciousness of objects. Sensory consciousness, perceptual consciousness, and comprehending consciousness are all subsumed under the heading 'consciousness,' since these forms of consciousness do not imply any knowledge the subject has of itself. Under the heading 'self-consciousness' are reviewed those forms into which some knowledge of the subject of consciousness of itself necessarily enters (desire and social recognition ('*Anerkennung*')). Finally, 'reason' is the consciousness of objects, in which it is comprehended that knowledge of general objects is only possible when the subject understands that the functions of his subjectivity constitute these objects in the first place. In conclusion, the higher cognitive performances (intuition, recollection, imagination, memory, and thinking) and voluntative ones (practical emotions, instincts, arbitrary acts, and striving for happiness) are discussed in *Psychology*. Within the 'free spirit,' the highest form of the subjective spirit, the attitude is reached and comprehended in which an individual knows of itself that it is only free and can only realize its freedom when it has overcome the dualism of interests that are merely of a theoretical or practical nature.

The *Doctrine of the Objective Spirit*, which Hegel has also worked out as *Elements of the* PR, comprehends the objective institutions in themselves, which men who know of their freedom give themselves – right in a narrower sense (property, contract, punishment of felonies), moral norms of acting individuals who strive toward the individual or collective good ('*Moralität*'), and the forms of social life in family, civil society, state, communities of states, and world history ('*Sittlichkeit*'). In order to accomplish this project, Hegel did not try to set up as large a set of consistent principles as possible, but instead conceived of concepts adequate to the subjects in question. The adequacy of the concepts is to be achieved by penetrating the fundamental conceptual material of effective norms and existing convictions of common sense and thus correcting the concepts.

Hegel's analysis of civil society has been especially influential (*see* Marx, Karl (1818–83)). According to this analysis, modern society tends to accumulate great wealth in the hands of a few, alienate workers in the working processes from their products and from themselves, press large parts of the population below the subsistence level, undergo times of over- and underproduction, form global markets, and colonize other countries. But at the same time, civil society implements institutions to administer justice, provide for the common welfare, and unite people in trade associations and municipalities. These institutions of society and others of the state make comprehensible how civil societies can develop and stabilize themselves to some, although not sufficient, degree in spite of their inherent tendency to crises. In his doctrine of state, Hegel tried to comprehend institutions that represent the general interests of a rational community and enforce them in the face of the special needs of estates and individuals of the civil society. So the state becomes the sphere of freedom that alone can guarantee the 'concrete freedom' of the individual of self-determination.

According to Hegel, world history, the doctrine of which makes up the final part of the PR, is constituted by the state. The principle organizing world history is the 'world-spirit,' the

process of the developing consciousness that *all* men as such are free. In this history, several states have made – to Hegel's mind – decisive contributions to this progress at certain times. In these periods, Hegel thought, they have the right – and indeed, the power – to politically and organizationally establish and expand a new principle. France was an example of Hegel's time: a country that had carried out a progress in the consciousness of freedom in its revolution and had expanded this new order through the Napoleonic Wars in great parts of Europe. But since the doctrine of the objective Spirit did not reach the highest form conceivable of freedom, Hegel's philosophy does not end with it, but rather with the doctrine of the absolute spirit.

Hegel's *Doctrine of the Absolute Spirit* is a doctrine of the three leading forms of spirituality in which men have at all times tried to understand what is significantly true and who they are within the whole of actuality that depends on such a 'Truth.' According to Hegel, these forms are art, religion, and philosophy. However, they have not always had the same importance since the time they came into being. Each form rather has its particular period in which it becomes the model form to exhibit the Truth. Hegel believed that for the ancient Greeks, art was the medium through which they best understood themselves and were able to express what they cherished most. For the Christians, religion was the best form for men to represent their relation to the Truth and the Truth itself. Both forms, however, have the drawback that their means of explication are at most somewhat discursive – or, indeed, not at all. It is the purpose of philosophy as a science to conceive the content of Christianity's true representations in an argumentative discourse and thereby to gain insight into the deepest reasons for which men come to agreement with each other and afford a stable basis for their life with each other. Therefore, Section Philosophy of the Real closes with a concept of philosophy, which is also to justify in retrospect the recognition carried out in the system of the philosophical sciences.

Some Lines of Reception in the Social Sciences

Lorenz von Stein (1815–90)

Lorenz von Stein was one of the most politically influential Hegelians among the theoreticians of society in the nineteenth century. With his diverse writings on modern society, he influenced central economic terms of Marx's theory (e.g., surplus value and accumulation) on the one hand, and considerably influenced Bismarck's social policy on the other. Up to 1933 he was studied by theorists of public and constitutional law (e.g., Georg Jellinek and Hermann Heller), a discussion that was continued in the German debates on the principle of the welfare state after the Second World War (Stein, 1972). Stein took up the question posed in Hegel's doctrine of '*Sittlichkeit*': how must a state be structured for the principles of the French Revolution to be realized considering the conditions of the industrializing society? He regarded the political constellation of his times as an unavoidable antagonism between the civil society based on the satisfaction of individual needs and the state aiming at general freedom. To his mind, this antagonism leads the propertied to try to occupy all state functions through unequal elections, in order to prevent the socioeconomical rise of the nonpropertied. Therefore, Stein thinks it to be the duty of a legitimate state and its institutions (monarch, officials, army) to implement social reforms resulting in a rise of the nonpropertied to the economical level necessary for them to participate in the process of forming a public will. In addition to this, the state should counteract the inequalities of the civil society by introducing universal and equal suffrage and guaranteeing basic rights. To this extent, Stein's doctrine of the state – like Hegel's – aims at more than just the guarantees of the liberal constitutional state, because it does not confine itself to the task of protecting the freedom of the individual from the state, but instead goes further to protecting the political freedom of the individual against the inequalities of the civil society through the state.

Karl Marx (1818–83)

In 1836, Karl Marx arrived in Berlin as a student 5 years after Hegel's death and had contact with members of the left wing of the Hegelians (*see* Marx, Karl (1818–83)). As Lorenz von Stein Marx started his reception of Hegel's PR by receiving and developing Hegel's arguments for a general and equal electoral law as a solution to the growing social question of his times (MEW, Bd. 1: pp. 320–333). This is one of the reasons why he confines his 'Critique of Hegel's Philosophy of Right' (1843) to a critique of Hegel's philosophy of state, which might have found some sympathies by Hegel as the latter had even publicly stated in one of his lectures about the philosophy of history, that there "still subsists a main one-sidedness, namely, that the *volonté générale* has to become also the *empirically* general will, i.e., that the individuals as such should reign or take part in reigning. […] It is this collision, this knot, this problem at which history stands [now] and which history has to solve in future times" (own translation: 12/534). According to Engels, Marx incorporated into his own Political Economy without any substantial critique Hegel's doctrine of the inherent instability of the development of a civil society if it is dominated only by pure laws of economics (MEW, Bd. 16: p. 326) as well as Hegel's dialectical method – cleansed from an allegedly Hegelian mysticism – into his own Historical Materialism (MEW, Bd. 40: S. 568–588; Bd. 21: S. 292; Bd. 23: S. 27 f.). Exemplarily for the first point, compare Marx's positive reception of Hegel's claim, that work contracts are illegitimate, if the employer demands of the employee all of his time of productivity, because in such a case the employee becomes the property of somebody else (PR Section 67; MEW, Bd. 23: footnote 164). But probably because of the factual consequences of the legislation concerning the poor in England and Germany as well as the political developments in Prussia since 1840, Marx underestimates the stabilizing potential of a combination of democracy and welfare state, which Hegel hinted at and Lorenz von Stein developed some steps forward. Exemplarily for this assessment, Marx seemed to have overlooked article 21 of the French Constitution of 1793 as well as Hegel's morally grounded and therefore overpositive, and also juridical right for a satisfaction of basic needs in a modern society (Enc.: Section 533). These might be some of

the reasons why Marx's ideas about a postrevolutionary society leave the field of Hegel's philosophy.

St Louis Hegelians

This American philosophical school was founded by William Torrey Harris (1835–1909) and Hans Conrad Brokmeyer (1828–1906). After the Civil War, this school was institutionalized by the foundation of the *St Louis Philosophical Society* (1866) and the *Journal of Speculative Philosophy* (1867). In contrast to the Transcendentalists at Yale and many of the German intellectuals, questions concerning religion did not play an important role for the St Louis Hegelians. Instead, questions concerning social justice in a modern society were central for them. In addition to this, another one of Hegel's basic interests became important again, on which, however, Hegel had only remarked in passing in his systematic works: how must pedagogy be in order to make the individuals growing up be able to competently participate in forming a free society? Besides being influenced by Hegel, Denton Snider (1841–1925) and Thomas Davidson (1840–1900), two St Louis Hegelians, were also influenced by the pedagogy of the German Friedrich Froebel (1782–1852) when they realized several educational projects: the *Communal University* in Chicago, the *Chicago Kindergarten College*, the *Goethe School* in Milwaukee, and the *Breadwinner's College* in New York City, which was devoted to the education of the working class. In 1889, Harris became the United States Commissioner of Education. Brokmeyer played a key role in the Constitutional Convention of Missouri in 1875, which guaranteed the right to education for all aged 6–20. Besides these important roles of the St Louis Hegelians in the formation of the modern educational system of the United States, the *Journal of Speculative Philosophy* offered a platform for the publications of important American philosophers such as John Dewey, William James, Charles S. Peirce, and Josiah Royce. Beyond offering this platform, they successfully animated the study of Hegel's philosophy (Flower and Murphy, 1977).

Wilhelm Wundt (1832–1920)

Wundt is commonly regarded as the founding father of Psychology, which established itself as a science around the beginning of the twentieth century. In 1879, Wundt founded the first psychological laboratory of the world in Leipzig, Germany, where he mainly studied sensations and feelings by employing experimental methods. This foundation also became influential outside Germany due to the many visits of foreigners – especially American students and scientists. Although Wundt often mocks the methodology of Hegel's philosophy, he explicitly praises Hegel's achievement of "denying the right to exist to all 'things in themselves,' whether they are to count as metaphysical borderline concepts or as practical postulates" (Wundt, 1911: p. 736). Without this Hegelian basis, it would have been impossible for Wundt to pursue psychology as an empirical special science, because the soul would have been withdrawn from the applicability of methods borrowed from the natural sciences, as long as it were conceived of as an independent substance removable from the body (Descartes) or were postulated as such on practical grounds (Kant). Hegel, on the other hand, "has regarded the individual soul as the immediate relationship of the experiences of the soul, as a piece of that infinite reality of the world spirit, which still draws only on its very own actual reality to obtain all that it means" (Wundt, 1911: p. 736). So Wundt arrives at the conclusion that Hegel "had also declared the liberty of psychology when it proclaimed for all that all mental coming into being – and, therefore, all happening in the soul as well – is actuality, is immediate experienced reality, and that essence and appearance of the Spirit are one and the same, and only mean something different in so far as we comprehend the essence as the relationship of the appearances which is correctly recognized" (Wundt, 1911: p. 737; own translations).

George Herbert Mead (1863–1931)

The posthumously published book *Philosophy of the Present* (1959) primarily promoted an interpretation of Mead's thinking that considers the last phase of it as on the way toward a speculative metaphysics of Hegel's kind. This is surely exaggerated. It is, nevertheless, possible to prove that Mead named Hegel as an inspirer of his own thoughts throughout his working period. Hegel's philosophy especially stimulated the scientific program of the young Mead. His early outline of a program of philosophical disciplines puts forward two main tasks of psychology, one of which was inspired by Hegel's PS: psychology is to give "an analysis of the objective world in terms of the consciousness of the objective individual" (Mead, 1900: p. 12). In pursuing this task, Hegel – according to Mead's view – e.g., proved that the organization of different characters, which constitute 'social objects,' comes from 'our mutual relations' (Mead, 1903: p. 106). In contrast to the explaining and describing psychology, logic is a normative science (Mead, 1903: p. 107), into which 'the general theory of the intelligent act as a whole would fall,' and which is supposed to be as such of Hegel's kind (Mead, 1900: p. 2). However, apart from this praise, Mead also continued to criticize Hegel's doctrines throughout his life: e.g., he falsely subsumed Hegel under the philosophy of romanticism, which, to his mind, only discussed the rationalization of bygone attitudes – quite contrary to the orientation toward the future of the American society and philosophy. Nevertheless, Mead praises Hegel's philosophy of history as "[t]he most grandiose attempt to combine the three great motives of speculation (that of Greek contemplation, that of the church's plan of salvation, and that of experimental science)" (Mead, 1964: p. 505).

Juergen Habermas (1929–)

In his essay *Can Complex Societies Form a Rational Identity?* (Habermas, 1976), which Habermas chose as the basis of his speech on the occasion of accepting the Hegel Award of the city of Stuttgart, Germany, in 1974, he explicitly classifies his proposal as standing in the tradition of Hegel's and Marx's thinking (p. 118). Although his interpretation of Hegel's answer to the question posed in the title of his essay is affirmative in many points, Habermas mainly criticizes – firstly – that for Hegel, 'only the idea of freedom' is to be conceived as a constituent of modern consciousness. In addition to this, 'the unrestricted objectifying thinking and a radical orientation toward the future' are also constitutive for it

(p. 105). Therefore, Hegel did not succeed in abolishing the threefold division between the modern subjectivity and external nature, society, and inner nature (p. 102) in all respects. Habermas objects, second, that modern society did not gain its rational identity in the constitutional state; he objects, third, that philosophy is unable to exhibit this identity as rational for all individuals – as religion has done in the past (p. 106 ff.). It is Habermas' opinion instead that modern societies could gain their rational identity in "the consciousness of the general and equal opportunities of participation in learning processes of forming values and norms" (p. 119) by realizing communicative structures 'by themselves,' in whose 'autonomy' alone a new collective identity can crystallize 'today' (p. 120; own translations). Critical remembrance of tradition, science, philosophy, and art propose rival identity projections (p. 121). However, later on, Habermas seems to have partially taken back his criticism of Hegel with his concept of 'constitutional patriotism' (Habermas, 1990). In addition to this, his interpretation of one of the rational functions of Right, namely, to relieve us from moral discourses (Habermas, 1996), can be understood as a continuation of Hegel's thoughts on the relationship of '*Moralität*' and '*Sittlichkeit*.' In 2008, Habermas has described his own philosophical development as 'my way from Hegel-Marxism to Kantian Pragmatism' (p. 78).

Abstract

Gramsci's concept of 'hegemony' has provided one of the most influential theoretical frameworks in contemporary cultural and media studies, and Marxist intellectual work in particular. Stated briefly, hegemony refers to a historical process in which the dominant group exercises 'moral and intellectual leadership' throughout society by winning the 'consent' from people. This concept has enabled cultural and media studies to explain not only the way in which the domination of a power group in modern capitalist societies is secured, but also how the dominant order can be challenged and contested through popular resistance directed in various cultural forms and practices. The applications of the concept of hegemony in cultural and media studies can be addressed in four distinct areas: the analysis of historical moments, the analysis of media texts, the analysis of subculture/popular culture, the analysis of audiences.

The concept of 'hegemony' has provided one of the most influential theoretical frameworks in contemporary cultural and media studies, and Marxist intellectual work in particular. While imprisoned by Mussolini's Fascist regime in the 1920s and 1930s, the Italian Marxist Antonio Gramsci developed the concept of hegemony to address the question of why the working class failed to make a communist revolution in the advanced capitalist countries despite Marx's prophecy. By 'hegemony', Gramsci (1971) intended to conceptualize the pivotal role of cultural persuasion in acquiring, exercising, maintaining, or challenging power without resorting to physical coercion. Stated briefly, the concept of hegemony refers to a historical process in which a dominant group exercises 'moral and intellectual leadership' throughout society by winning the voluntary 'consent' of popular masses.

The Concept of Hegemony

The concept of hegemony can be more effectively understood when it is compared to Gramsci's notion of 'domination,' as each term represents a different kind of power. Whereas domination rests on a dominant group's coercion of the less powerful, hegemony relies on a dominant group's ability to procure subordinate groups' consent to the existing social order. Domination belongs to the state, which Gramsci called 'political society,' and is equipped with instruments of coercion such as the police and armed forces. In contrast, hegemony takes place in the realm of private institutions – including those outside of the spheres of economic production and the state, such as families, churches, trade unions, and the media – which Gramsci called 'civil society.' Gramsci attributed the political stability and obedience of the working class in Western European countries to the hegemony built into the vigorous civil societies of those countries. Consent and coercion always coexist, but typically, dominant groups in contemporary capitalist societies rule through hegemony unless severe social and political crises require directly coercive interventions.

The Concepts of Consensus and Historical Bloc

The essence of the concept of hegemony lies in the idea of subordinates' consent. According to Gramsci, the consent of subordinates is constructed when a dominant group's particular world view is accepted by the subordinate groups as their world view, and thus the dominant group's interests appear to be the interests of the society at large. As a result, the dominant group is seen as entitled to its ethical and intellectual leadership and arises as a hegemonic group in a particular historical period. Moral and political authority legitimated by popular consent characterizes hegemony as power from below, distinguished from power wielded by coercion or by manipulation from the top down.

However, the paradox of subordinates' consent to their subordination in the long run raises suspicions about the nature of popular consent (Lears, 1985). Indeed, some critics of the concept of hegemony have questioned how subordinates can give consent to what will adversely affect their interests unless they are self-deceived in false consciousness. The very idea of 'false consciousness' threatens to undermine the concept of hegemony in at least two ways. First, if one accepts the idea of false consciousness as the basis of popular consent, subordinates' consent is the outcome of sheer manipulation, and Gramsci might be accused of elitism for his implicit assumption that the popular masses are dupes. Alternatively, if one rejects the idea of false consciousness by arguing that people know the purpose of their actions and consistently base their actions on rationally determined self-interest, then the consensus may represent genuine or true consensus. Then, the characteristic of hegemony as dominance over subordinates would be invalidated, and their actual grievance or resistance may slip from view.

Both Jackson Lears (1985) and Stuart Hall (1996a) responded to this dilemma by rejecting the binary opposition of false and true consciousness in understanding the nature of consent. They instead embraced Gramsci's idea of 'contradictory consciousness' grounded in 'common sense.' According to Gramsci, common sense as everybody's spontaneously arrived at philosophy constitutes the popular masses' practical consciousness guiding their actions. However, 'common sense' is fragmented and contradictory; the human conception of the world is 'disjointed and episodic' rather than 'critical and coherent' (Gramsci, 1971, p. 324). Gramsci's conception of 'contradictory consciousness' as the condition of humanity makes it possible to understand that human action does not

 http://dx.doi.org/10.1016/B978-0-08-097086-8.95055-4

always result from fully conscious free choices based on rational calculations. Individuals' subtle subjective meanings and psychology also lead human action. So, without subscribing to the idea of false consciousness, one can understand popular consent in this broader picture of human beings whose consciousness may be 'contradictory,' but not 'false' (Lears, 1985; Hall, 1996a).

The formative process of hegemony, for Gramsci, also involves a 'historical bloc.' According to Gramsci, a historical bloc means an alliance of disparate groups or class fractions which is bound not only by shared economic interests but also by a particular world view, understood as ideology which cements varied classes and groups into a unity of collective will. An instance of the successful formation of a hegemonic historical bloc is found in the French Revolution of the eighteenth century. According to Gramsci, the French revolution was possible because the Jacobins were able to bring the French bourgeoisie class fractions and the great popular masses together under discourses of 'equality, fraternity, and liberty.' These discourses were not just the bourgeois class's language circulating only within its own circles, but also the popular masses' words reflecting the exigencies of their time in the French cultural tradition. By identifying the interests of the bourgeois class with the general interests of all the national forces in French society, the bourgeois class was able to form a historical bloc, and to exercise the intellectual and moral authority to lead the masses toward the revolutionary struggles. This case also makes clear that ideology plays a crucial role in building a historical bloc through both economic and spiritual solidarity.

In this vein, hegemony seems to represent the most effective and formidable means of exercising power. Steven Lukes (1974) argued that a significant layer of power is found in the ability of powerholders to affect and modify the desires and beliefs of the powerless to the extent that resistance from the powerless cannot easily take place. With regard to the concept of hegemony, this view of power highlights the cultural dimension of power and offers insights into the acquiescence of subordinates under hegemonic consensus (Gaventa, 1980). However, this view may unwittingly generate the impression that hegemony is such an unconquerable, overarching form of power that it can prevent subordinates' possible resistance in the first place by saturating their consciousness with hegemonic ideologies. An important question follows from this impression: 'Is popular resistance really possible, and if so, what makes it possible?' This question reflects Gramsci's foremost concern. In explicating the concept of hegemony, Gramsci constantly emphasized the instability of hegemony, and enthusiastically proposed the possibility that subordinate and popular groups may form 'counterhegemonies.' The idea of counterhegemony suggests Gramsci's vision of social change embodied in the concept of hegemony itself.

Hegemony, Cultural Resistance, and Social Change

The question of where power lies is closely related to an interest in the source of change and in the ways of making a difference in history for practical and political purpose (Lukes, 1974). Gramsci understood popular consent as the locus of, as well as a means of, subverting hegemony, and as a strategy for historical social change. Hegemony is not a complete state or system but a historical process which needs "continually to be renewed, recreated, defended" and is also "continually resisted, limited, altered, challenged by pressures" (Williams, 1977, p. 112).

What, then, may be the grounds for the possibility of alternative or counterhegemony? For Gramsci, common sense makes it possible for subordinates to come to occasional understandings of the conditions of their subordination and exploitation. By combining common sense with the coherent philosophy of the intellectual class, subordinates can constitute themselves as historical agents. Then, common sense turns out to be a strategically important terrain of ideological struggles. Since popular masses make sense of their world and themselves through common sense, various groups and classes compete over moral and intellectual leadership in this terrain.

The concept of a historical bloc also opens up the possibility of forming a national-popular alliance led by subordinate groups for an alternative or a counterhegemony. Discussions about a historical bloc in counterhegemony have been extended and elaborated by Ernesto Laclau and Chantal Mouffe (1985) and Stuart Hall (1996b). According to them, the principle underlying hegemony is 'articulation,' which refers to the practices of linking disparate groups, disparate ideologies, or various forces into a unity. In other words, a historical bloc is the very outcome of articulations.

Utilizing the concept of articulation, Laclau and Mouffe argue that there is no necessary, intrinsic tie between ideologies and classes, as assumed in such terms as, 'bourgeois ideology' or 'working class ideology.' Rather, certain ideologies come to serve certain groups' or classes' interests, and represent the world view of members of a class as a result of their efforts to articulate ideologies according to their own interests. In the French Revolution, for example, the Jacobins succeeded in articulating the ideology of 'liberty and equality' to the bourgeois class. Therefore, Laclau and Mouffe believe that subordinate groups such as women, people of color, ethnic minorities, and others can also enlist the ideology of liberty and equality to carry out a new, radical, democratic project in contemporary capitalism. This project implies that the working class is not exclusively responsible for the task of social and political transformation. That is, in contemporary modern society, relations of dominance and subordination do not hinge solely on the axis of class; the concept of a historical bloc as a strategic alliance can be applied to the strategies of 'all' classes and groups (Laclau and Mouffe, 1985; Hall, 1996b, p. 425). Moreover, individual human subjectivity and class identity are not a priori fixed and unified. Rather, individuals and groups negotiate and construct their own identities in the articulatory practices of hegemony.

Laclau and Mouffe and Hall have not so much diverged the theory of hegemony as they have returned to Gramsci's argument that people, as the ensemble of social relations and thus as contradictory subject, 'create their own personality' (Gramsci, 1971, p. 360). In the concept of hegemony, the popular masses' ideological struggles and cultural resistance to form a collective will against the existing hegemony constitute the essential base of social and political change.

The Implications for Theories of Culture

The concept of hegemony marks a groundbreaking departure from classical Marxist understandings of culture, which stand on the 'base-superstructure' model. According to this model, the economic foundation of society, called the 'base,' determines the social, political, cultural life processes called the 'superstructures.' Related to this model is the proposition that the dominant ideas in a given society are the ideas of the economic ruling class. Upon these propositions, the complexity of culture is conceived of as a pale reflection of the economic imperatives of capitalism, and as an expression of the interests of the ruling class. In this line of thinking, culture is understood in terms of 'ideology' which was identified with 'false consciousness.' Therefore, cultural theories in the Marxist tradition have been underdeveloped and often limited to critiques of ideology.

In this context, Gramsci's concept of hegemony has brought remarkable changes to the understanding of culture. In the concept of hegemony, culture takes on a fundamentally important, formative role. Culture is grasped as a complicated, contradictory, multilayered sphere in which ideas and values are materialized in the forms of varied institutions. With the concept of hegemony, Gramsci significantly reformulated the relations between base and superstructure as dialectical interactions rather than a one-way causal determination, and emphasized cultural struggles. Therefore, he could establish the understanding of the relative autonomy of culture from the economic base, and effectively overcame the classical Marxist tendency toward both economic and class reductionism of superstructures.

In this regard, Raymond Williams, an influential Marxist literary critic, convincingly argued that, by conceptualizing culture as 'a whole social process' and by connecting it to the power relations of domination and subordination, the concept of hegemony dialectically develops two powerful earlier concepts, 'culture' and 'ideology' (Williams, 1977, p. 108). The concept of counterhegemony also emphasizes the relative autonomy of politics from the base, and facilitates the recognition of nonelite classes as agents of historical and political change.

Applications of the Concept of Hegemony in Cultural and Media Studies

Cultural and media studies have applied the concept of hegemony to understand and analyze the roles and meanings of various cultural and media forms and practices. Several of these applications are briefly described in the following four areas: 'journalism,' 'textual analysis,' 'subcultures,' and 'audiences.'

The Analysis of Journalism

A seminal work relying on Gramsci's concept of hegemony emerged from British cultural studies. Stuart Hall et al. (1978) argued that the radical right in the 1970s was able to reintegrate the crisis of the social–democratic consensus into a new 'law and order' framework and smoothly usher in Thatcherism. Underlying the reconstructed popular consent was a moral panic against social crime like mugging. The moral panic, created through the work of the mass media as well as judiciary practices, was interwoven with racist bias, further mobilizing popular anxiety. This work demonstrates the ideological work of mass media as well as that of the state in recovering hegemony (see British Cultural Studies).

In the USA, Todd Gitlin (1980) took up the concept of hegemony as a theoretical framework to explain the relationship between the US news media and social movements in contest with broad popular consent in the 1960s. He illuminated how commercial news 'framed' the antiwar movement in ways that 'trivialized' and 'marginalized' it, and consequently how the New Left finally failed to control the public cultural space. According to Gitlin, news is a way of interpreting, organizing, and presenting the news, and it is a routine journalistic practice rooted in journalists' professional beliefs. Through this framing practice, the news media tend to implicitly define dissident social actors as illegitimate, and to deflect, absorb, and domesticate oppositional or conflicting ideas in ways that reinforce the hegemony. For instance, journalists reported on antiwar student leaders as they would report on celebrities, since this 'celebrity frame' met their need for spokespeople, based on the code of objectivity and concern for the newsworthiness of the story. Furthermore, this frame could also satisfy the commercial media's preference for the human interest angle. However, the impact of this frame on the student leaders was devastating. Subject to the glamor and pressures of popularity under this frame, the leaders became estranged from the movement base, and the movement itself gradually lost control of its own leaders. As a result, despite their original intention to use the media to reach the great popular masses, the antiwar movement failed to obtain popular consent (see Media and Social Movements).

If news framing is a routine practice, then how can news frames be changed? If commercial news frames maintain hegemony, as Gitlin concluded, one must look elsewhere for possible conditions for social change. Daniel C. Hallin's (1989, 1994) work on US coverage of the Vietnam war and of the conflicts in Central America offers valuable insights. By tracing shifts in news framing, Hallin identified dynamic relations between the news media and the dominant political group, which underlay the competition of different frames for a hegemonic presence. According to Hallin, depending on the degree of consensus among the political elite, news coverage of war took on different frames. Hallin stressed that journalistic routines relying on official sources (e.g., press conference) tend to constrain the media's consensus over the frame to the boundaries of the hegemonic view. But he also convincingly argued that when the hegemonic group reveals cracks in the political power bloc, the media become more critical and independent, and journalist routines break down. As a result, dissident views and groups can be framed more positively, until the hegemonic group, recovering its unity, actively engages in repairing the boundaries of general consensus in society. These analyses of journalistic routines and news framing successfully connect the microlevel sociology of journalism with the macrolevel politics of hegemony, and simultaneously suggest the possibility of social change.

Tamar Liebes (1997) shed light on another dimension of journalists' voluntary consent to the hegemonic social order. According to her work on Israeli media coverage of the Arab–Israeli conflict, Israeli journalists genuinely believe in the necessity of censorship for national security and, as a result, they actively compromise their ideals of free speech and professional autonomy by colluding with military censorship. Thus, journalistic 'self-censorship' of news routinely takes place before any forceful, formal official censorship actually occurs. Despite the fact that Israeli journalists self-consciously perform self-censorship, interestingly enough, they are rarely seen as either manipulators of public opinion or conspirators with hegemonic power. Rather, as Liebes showed, the journalists' consent to Zionism as a dominant ideology was formed and internalized throughout their life experiences in the Israeli culture and history; that is, the journalists are both part of the community and members of the elite group. The discussions of Gitlin, Hallin, and Liebes on the practices of journalism are distinguished from the instrumental view which considers the news media as a tool for the privilege group. For example, Edward Herman and Noam Chomsky (1988) argued that the media are a propaganda system which is controlled and directly manipulated by the elite so as to benefit the powerful and the state. Their approach ignores the decentered hegemonic process which Gitlin, Hallin, and Liebes argued by revealing the dimension of journalist acculturation as well as socialization in news organization.

The Analysis of Texts

The concept of hegemony has influenced the theories and practices of 'textual analysis' by conceptualizing texts as site of struggles over meaning, not as means of inculcating dominant ideologies. Textual analysis in cultural studies has been applied to various cultural forms and practices, in particular film and television in media studies. It has significantly contributed to the understanding of ways in which dominant meanings are encoded in cultural products so that readers take the established social order for granted. In many textual analyses, however, audiences were often assumed to be passive and vulnerable to dominant ideologies; texts, especially the mass media, were easily credited with powerful ideological effects. Many textual analyses tend to read the ruling class's or state's successful hegemonic process directly from the text, to privilege the researchers' perspective, or to easily assume subordinates' consent (Condit, 1994). These limitations may become serious in cases where rearchers endorse language-centrism to the extent that only language and its structure determine human subjects and power struggles, apart from texts' meanings in peoples' real social life process which Gramsci relentlessly emphasized.

Studies of Subculture and Popular Culture

The concept of hegemony provided a key theoretical framework to British subcultural studies in the 1970s. Subcultural studies inquired into the everyday life of the young working class and the meanings of their cultural consumption in a framework of power inequality (Hall and Jefferson, 1976; Hebdige, 1979). The researchers were primarily concerned with the styles of youth subcultures in the UK such as mods, rockers, teddy boys, and punks. According to them, these teenagers actively create their styles by appropriating various symbols out of consumerism to construct and express their identity and to resist the hegemonic social order. In this view, styles are not only sites for negotiating meanings but also forms of cultural resistance built in lived experience, although not all of their responses prove potentially counter-hegemonic. This body of work on youth cultures takes popular culture seriously as the terrain of symbolic struggle, which is not necessarily bound to the economic class struggle (see British Cultural Studies).

Research on long-term consequences of youth subculture on power relations by Paul Willis (1977) fascinatingly demonstrated how working-class boys' counterschool culture prepares them for reproducing themselves as laborers. Although Willis did not employ Gramscian terminology, this work may deepen the understanding of hegemony. In this ethnographic work, Willis observed that the schoolboys' resistant practices, intertwined with the dominant values of masculinity as patriarchal ideology, ultimately produced their concession to the existing power relations. In such a case, any simple dichotomy of 'resistance' and 'hegemony' becomes problematized, and the line between them blurred. Willis showed that hegemonic consensus contains very contradictory and uneven processes with unintended consequences, which refutes any necessary correspondences between consciousness, practices, and material conditions.

Recent applications of the concept of hegemony to subculture and popular culture seem to be located in a broader cultural matrix than the earlier British subcultural studies embedded in the context of 'English culture.' Focusing on race, gender, ethnicity, class, age, and other axes of cultural subordination, studies of subculture and popular culture have examined the complicated process of cultural politics. For example, rap music is not simply a music for the young. It is an important form of young black cultural resistive expressions in the USA. Black urban male rap artists strenuously attempt to delegitimate powerful social order by criticizing racism and police brutality on blacks; but at the same time their lyrics often reflect sexist, homophobic, or anti-Semitic ideas (Rose, 1994). Cultural politics hardly proceed without contradiction.

The Analysis of Audience

After the influential Marxist linguist Mikhail Bakhtin argued compellingly that language innately bears a multiplicity of voice in conversation, the understanding of the monolithic and predetermined ideological role of texts has come under criticism. Following this, abundant interest in audiences' interpretations of texts has flourished in cultural and media studies. With regard to the concept of hegemony, this interest seems promising to provide substantial empirical evidence about popular consent, culled from audiences' actual interpretations of symbolic work.

A theoretically significant model sparking the emergence of critical audience studies was proposed by Stuart Hall's (1980) 'Encoding/decoding.' He suggested three decoding positions, i.e., 'dominant-hegemonic,' 'negotiated,' and 'oppositional' positions in which the accommodation of hegemony and popular struggles over meaning can be simultaneously considered. These reading positions help to identify whether audiences read a text according to the way that the message is 'dominantly' encoded, or in an 'oppositional' way although they would understand the dominant meaning preferred by the producers of the message; or, they generally accept the dominant meaning of the text but partially read against it in a 'negotiated' way of reflecting their own interests (see British Cultural Studies; Audiences, Media). Building on this model, David Morley (1980) launched a landmark work on audience reception of a British news magazine television program. In this work, Morley, who was primarily interested in workingclass audience interpretation of the program, concluded that neither text nor audiences' social class directly determine audience readings. After his work, audience research proliferated and has provided evidence that audiences are capable of interpreting texts oppositionally or alternatively based on their own social experiences, and of using texts for their own purpose.

The shift of focus from the text to the audience and from ideology to cultural resistance runs parallel to increasing interest in counterhegemony in the context of everyday life, although some research has been criticized for its tendency to celebrate audience autonomy without evidencing any substantial social consequences (see Audiences, Media).

Cultural and media studies since the 1980s tend to be theoretically more synthetic, including Gramsci's concept of hegemony together with other postmodern theories, and have drawn more attention to issues of identity politics. Noticeably, scholars outside of the Anglo-American context have increased their presence in English-speaking forums, and have enriched cultural and media studies. For example, deeply engaged with the concept of hegemony, Néstor García Canclini (1995) and Jesús Martín-Barbero (1993) have offered valuable elaboration on the development and complexity of popular culture, and on the active struggles for the formation of new cultural identities in Latin America. Case studies of Mexican film, Brazilian popular music, and the *telenovela* illuminate how the melodramatic and cultural imaginations of the popular classes in everyday life are articulated popular with cultural memories as a way to form new cultural identities (Martín-Barbero, 1993).

Gramsci's concept of hegemony has been continually reinterpreted and applied to different areas of cultural and media studies, depending on the immediate social and cultural questions of theorists in specific social and historical contexts. However, all research relying on the concept of hegemony shares a common pursuit in criticizing culture as a source of control, and, simultaneously, in envisioning it as a source of resistance.

Abstract

Anthropologists commonly cite Antonio Gramsci when they refer to hegemony and the related ideas that make up Gramsci's neo-Marxist theory of hegemony, such as culture, common sense, and the intellectuals. However, most anthropologists are inspired by interpretations of hegemony other than Gramsci's. To understand how anthropologists understand and use the idea of hegemony, it is essential to know how Gramsci's idea of hegemony as a moral and intellectual leadership was revised by non-anthropologists and equated with ideas of culture, tradition and ideology. By the time anthropologists discovered the idea of hegemony in the late 1980s it barely resembled Gramsci's. Because of the various interpretations and different applications of hegemony, hegemony has for many anthropologists been only a trendy buzz word that negates its political intent. Yet other anthropologists have seriously applied the idea of hegemony in diverse, novel, and creative ways in order to explore primarily two related concerns: the historical consequences of state and colonial policies for contemporary post-colonial societies, and relations of resistance and political domination. After briefly considering how Gramsci conceived hegemony and how others revised it, these two concerns provide the focus here for the anthropological use of hegemony.

Introduction

By the time anthropologists discovered Antonio Gramsci's idea of hegemony in the late nineteen eighties, it had been reworked by others so that it barely resembled Gramsci's. Although anthropologists cite Gramsci's *Prison Notebooks* (1971) when they refer to hegemony, most are inspired by revisionist interpretations of hegemony.

Hegemony

Hegemony is the central idea among many by which Antonio Gramsci established a humanistic, neo-Marxist approach to revolutionary change. Instead of subordinating the superstructure of ideas to the force of the economic base, Gramsci empowered the influence of ideas over Marxism's economic determinism. At the core of Gramsci's methodology is the dialectical relationship between hegemony (consent-support) and domination (coercion-force). His primary theoretical concern was how to resolve this contradiction, for in political practice one is always tempered by the other. He tried to reach resolution in part by redefining hegemony.

Lenin defined hegemony as domination. Gramsci redefined it as an *intellectual and moral leadership* directed by contradictory political and cultural agents and organizations he called *organic* and *traditional* intellectuals. Organic intellectuals represented the interests of working classes. One of their tasks was to make the proletariat aware of capitalist domination and exploitation. Traditional intellectuals represented the interests of the bourgeoisie. One of their tasks was to quell counter-hegemonic resistance to capitalism.

More than other Marxist thinkers, Gramsci recognized the significance of culture in revolutionary practice. Gramsci defined culture as 'the exercise of thought, the acquisition of general ideas *the habit of connecting cause and effect* … enlivened by organization' (Kurtz 1996a, 1996b). Culture was central to Gramsci's political strategy. He argued that culture was a political product of intellectuals, for another of their tasks was to develop the people's culture through education and ideological indoctrination. Traditional intellectuals worked to convince people of the virtues of capitalism and obtain their consent to capitalist rule. Organic intellectuals worked to help people develop an alternative to a capitalist culture. Among other strategies, Gramsci suggested how organic intellectuals might use popular cultural forms and signs to marshal working class revolutionary energies, depose capitalism, and construct a unitary proletarian culture.

Revisionists

Of the many works that explore Gramsci's thinking (Kurtz 1996a), anthropologists rely largely on those of Williams (1977) and Laclau and Mouffe (1985). Williams is concerned with the relationship between culture and hegemony. He argues that hegemony goes beyond culture, is synonymous with culture, serves as a form of 'cultural domination,' and, as a structure of cultural forms, provides a repository for traditional values. But, by equating hegemony with tradition, Williams divests it of Gramsci's political specificity.

Laclau and Mouffe are concerned with the heterogenous social organization of contemporary capitalist nations. They equate hegemony with ideology grounded in discourses by which oppressed categories in capitalist societies – women, gays, ethnic categories, and the like – can be made aware of their oppression. For Laclau and Mouffe hegemony (read ideology) provides the 'organic cement' of political formations that will transform western capitalism into a 'radical socialist democracy.'

These authors appropriated Gramsci's idea of hegemony and made themselves its authority, yet little that they say corresponds to Gramsci's idea of hegemony. They also ignore

the role of intellectuals in political practice. Still, the beauty and bane of their interpretations are the extent to which hegemony becomes amenable to diverse interpretations by anthropologists, but sometimes at the cost of the political intent with which Gramsci imbued it.

Anthropology and Hegemony

Anthropologists were attracted to the idea of hegemony for several reasons. It provided a neo-Marxist approach that complemented the idealist orientation among anthropologists who emphasize the power of ideas over material forces; it provided a new way to explore political relationships; it enabled reconsideration of old ideas, such as culture. Above all, it was thought provoking. Consequently there is little consistency regarding how anthropologists use it.

Most often anthropologists use hegemony as a trendy buzz-word that dilutes the concept's power. The idea of hegemony becomes more complicated when anthropologists use it seriously to analyze political relations. Only rarely do anthropologists use Gramsci's definition of hegemony to explore relations of domination and subordination. Instead, most anthropologists cite Gramsci, if only in passing, as the source of the idea of hegemony. Then they relegate his idea of hegemony to a secondary status and make it a point of departure to use or develop other interpretations of hegemony (Kaplan and Kelly 1994, Kurtz 1996a).

As a tool for analysis, anthropologists most often equate hegemony with a political force in society which usually emanates from those in power. Some anthropologists use revisionist ideas of hegemony to focus on other of Gramsci's ideas, such as *common sense* (peoples' awareness of their condition) (*American Ethnologist* 1993). However they approach hegemony, anthropologists infer that a hegemony of the proletariat to counter domination is rare (*American Ethnologist* 1993, Kurtz 1996b).

When anthropologists explore the relationship between hegemony and culture, it is Williams' ideas of hegemony and culture, not Gramsci's, that informs these explorations. Others use Laclau and Mouffe's idea of hegemony as ideology in conjunction with Williams' ideas of hegemony as culture and tradition to rework Gramsci's ideas. In these instances anthropologists become the source and authority of new ideas of hegemony. Almost no anthropologist places either hegemony and domination or traditional and organic intellectuals in the dialectical context that Gramsci thought to be important in hegemonic encounters.

This diversity of application of hegemony by anthropologists can be explained by their frequent argument that Gramsci did not define hegemony clearly. It is true that Gramsci's *Prison Notebooks* are fragmentary and open to interpretation. But anthropologists also do not read the *Notebooks'* informative footnotes, Gramsci's preprison writings, or the authoritative exegetes of his work. As a result they privilege others' interpretations of hegemony. Regardless how anthropologists define and locate hegemony theoretically, it is most applicable to two related concerns: the consequences of state and colonial policies and political relations of domination and subordination.

State-Colonial Policies

Only a few anthropologists apply Gramsci's formulation of hegemony to explore the impact of colonial policies. Carstens (1991) used Gramsci's idea of hegemony to account for how unequal relations between dialectically opposed intellectuals, British missionaries and Okanagan Indian chiefs, changed Okanagan culture and relegated the Indians to an inferior economic status in contemporary Canada. Kurtz (1996b) extrapolated from Gramsci's idea of hegemony to develop the idea of *hegemonic culturation* to explain why political leaders strive to instill an ideology of work in their political communities and why resistance to these efforts is rare.

More commonly, analyses rely on Williams' idea of hegemony as cultural domination. Fox (1989) used Williams' idea of hegemony as culture to explore how cultural meanings arose in colonial India and compelled colonizer and colonized to conform to certain behaviors. Contrary to Williams, hegemonic agents are central to Fox's idea of hegemony. He demonstrates how intellectuals continually experiment with existing cultural meanings which both enable and constrain resistance to colonial rule. But hegemony is not a source of revolutionary change for Fox. Instead, as Williams' cultural domination, hegemony continues to subordinate behaviors to the meanings it encodes.

In analyzing cultural confrontations in colonial South Africa, the Comaroffs (1991) emphasize Williams' ideas of hegemony as tradition, and Laclau and Mouffe's idea that discourse has the power to transform indigenous culture. For the Comaroffs, hegemony represents a tradition which, through discourses, acquires an ideology that helped to reorganize indigenous South African societies in accord with colonial rule. Ideology, not hegemony, provided the force of change. As tradition, hegemony had power only to shape actions, perceptions, and changes to the extent that it provided the source of new ideological challenges to existing traditions. As a process, hegemony (read tradition) is reproduced by its interplay with ideology into a functionalist 'hegemonic order' that provides a repository from which cultural forms may be created through the discursive power of ideology.

Domination and Subordination

Anthropologists who analyze the impact of state and colonial policies on anthropological subjects do not ignore the relationship between resistance and domination. Domination and subordination are implicated in almost all application of hegemony. But anthropologists who emphasize these relations explore them largely in post colonial and authoritarian societies, such as Sri Lanka and Bolivia, through ideas of hegemony that are largely of their own making. They agree only that hegemony is always a process.

Among these explorations hegemony is perceived as a *synthesizing principle* for welding class interests into a coherent world view (McDonogh 1991). In another context hegemony is a *social process* embedded in discourses aimed at instilling an ideology of nationalism (Brow 1988). The persistence of patron-client relations is maintained by hegemony identified as a *force* that maintains a social structure through the cultural shaping of experience (*American Ethnologist* 1993).

Hegemony, conceived as a *historical moment*, explains how a ruling class shapes perceptions of ideas, such as female beauty, to legitimate their rule over the working class (*American Ethnologist* 1993). Some anthropologists load the idea of hegemony with an array of theoretical considerations. In one instance, hegemony functions as the source of *education* for Gramsci's idea of 'common sense' (Woost 1993). In another it represents an ongoing *formative process* that may promote resistance to domination (*American Ethnologist* 1993).

Most anthropologists who consider the role of agents in these relations emphasize the role of elites, and argue that proletarian agents are not very effective in developing counter-hegemonies. Even those few anthropologists who emphasize the role of working class intellectuals in confrontations with elites conclude that proletarian intellectuals have little impact on changing the sources of rule and domination. As Laclau and Mouffe suggest, this is because the proletariat is too alienated and submerged under a dominant culture and rule. A logical consequence of this tendency is to privilege hegemony as tradition and render it apolitical.

Although anthropologists use hegemony as understood by others than Gramsci, and often in more convoluted fashion, they tend to agree on what could only be disheartening to Gramsci: the hegemonic impact of colonial and some contemporary governments has sufficiently restructured the culture and society of subordinate peoples that counter-hegemonies to domination are difficult to attain. Hegemony, however conceived, seems to accommodate best the interests of the elites.

The Future of Hegemony in Anthropology

The concern of anthropologists with the idea of hegemony peaked in the early 1990s. Now hegemony is firmly ensconced in anthropological discourse and theoretical orientations concerned with culture, structuralism, a poststructuralism *cum* postmodernism, even a revised historical materialism that objectifies ideas as material forces. Regardless how anthropologists conceive hegemony, it holds a privileged place among a cadre of non-materialist, neo-Marxist anthropologists and provides them a humanistic methodology to explore novel cultural and political relations. The collapse of the Western European and, more recently, Soviet empires and the energy of the expanding world capitalist order have produced global disjunctions in social, cultural, economic and political relations. To explain these epiphenomena, anthropologists are likely to continue to develop creatively the explanatory power of the idea of hegemony.

Abstract

Fritz Heider is the originator of two dominant theories that have impacted a number of research areas within the social sciences, particularly psychology. These conceptions, labeled balance theory and attribution theory, were most visible during the 1960–1980 decades, following the publication of his groundbreaking book *The Psychology of Interpersonal Relations*. This article traces Heider's life, discusses his contributions to social science, and reviews some of the fields of research influenced by his ideas.

Fritz Heider was born in Vienna on 19 February 1986, the younger of two sons, and spent his childhood in Graz in the province of Styria (Steiermark), Austria. There he received a classical education at the state official Gymnasium. Unable to serve in the army during World War I because of the loss of vision in one eye due to an injury during childhood, he entered the University of Graz (where ironically at one point he studied depth perception). He did not have a professional goal in mind and in the European tradition attended a wide range of lectures available to all university students. His studies eventually centered on philosophy and psychology (in opposition to the pursuit of architecture or law desired by his more practical father, who urged him to have his other interests as hobbies rather than a life focus). Heider remained a student at Graz for his entire university training.

While at the University of Graz, Heider made contact with Alexius Meinong (1853–1920), an influential figure in European philosophy. Meinong was a student of Franz Brentano and came to Graz as Professor of Philosophy in 1882. He taught courses in experimental psychology and established the first psychological laboratory in Austria (in 1894) as well as the Graz school of Gestalt psychology. Heider also was influenced by the psychologist Vittorio Benussi (1846–1928), a student of Brentano and Meinong and among the first to conduct and publish experiments in the field of gestalt perception.

It was Meinong who suggested the topic of Heider's (1920) doctoral thesis with the obscure question: "Why do we say we see the house rather than the sun, for the reflected rays of sunlight are the stimuli that actually strike the eye?" Understanding this question, and the analysis and answer provided by Heider, offers insights into attribution theory, one of Heider's contributions to the social sciences. Heider's solution to Minong's question was to provide a variation to the so-called causal-representational theory of perception, which was known at that time. Heider accepted that objects of perception are not directly perceived but are inferred as causes of the sensations they produce. He contended that aspects of the environment differ in terms of stability and causal potency. Things, or distal stimuli, are relatively stable centers of causality; they are objective structures in the environment. Media, on the other hand, or proximal stimuli, are more variable parts of the environment providing information about things. These ambiguous symbols require decoding and vary depending on environmental conditions. Heider proposed in his dissertation, entitled *Thing and Medium*, that thing perception is a complex causal inference process, reconstructing the relatively constant environmental centers of causality from sensations by filtering out the causal effects of the media. He believed in a 'real world,' with the task of the observer to come to know this reality. Heider later carried these ideas into his analysis of person perception and dispositional inferences, thereby unifying some aspects of object and person perception.

After finishing his dissertation, written in 1919, Heider worked for a year as an applied vocational psychologist. But he soon became restless and moved to Berlin, where his uncle worked as a zoologist. At the suggestion of Benussi, he contacted the psychologists at the University of Berlin, the center of Gestalt psychology (a school of thought based on the principle that perception is dependent upon the environment in which the object is embedded and perceptual experiences cannot be explained by the mere sum of the component parts). An air of excitement permeated the Berlin department of psychology. The lectures in perception, especially those of Max Wertheimer, were popular among students and intellectuals from widely differing fields. There was the feeling that gestalt research and theory would have an impact on the development of psychology. Heider attended the lectures of Wertheimer as well as those of Wolfgang Kohler and Kurt Koffka. He also formed a lasting intellectual and personal friendship with Kurt Lewin, a younger member of the Berlin faculty. Lewin, in turn, had been influenced by Ernst Cassirer, one of Germany's rising young philosophers. Cassirer left Berlin for the University of Hamburg in 1919, prior to Heider's arrival, but he indirectly affected Heider via Lewin and more so later when Heider also moved to Hamburg.

After Berlin came the *Wanderjahre*, a period when Heider spent a good deal of time meandering while reading philosophy, especially Spinoza (who guided his subsequent reasoning about emotions) and Nietzsche, as well as literature and psychology. He also worked in an orphanage and later was supported by a caring uncle. In 1927, after he had returned to Berlin, Heider became an assistant to Wilhelm Stern (1871–1938) at the University of Hamburg, whose primary contribution to psychology was in intelligence testing (he coined the term IQ). During this time, Heider also came to know Heinz Werner as well as Cassirer.

Heider then experienced a major shift in his life and career. Kurt Koffka was on an extended fellowship conducting research

at Smith College in Northampton, Massachusetts, and needed an assistant. Stern recommended Heider, who accepted what he regarded as a 1-year position in the United States in 1930. Heider's principle appointment was at the Clark School for the Deaf, where Grace Moore was also a member of Koffka's research group and was one of the first persons Heider met in America. They were married shortly thereafter and Heider remained in the USA.

In the years that followed, Heider combined research at the School for the Deaf with teaching at Smith College, where he was an Assistant Professor. He published two monographs jointly with Grace Moore on the psychology of the deaf. The methods he devised to study deaf children inspired a well-known silent film Heider later made with Marianne Simmel that captured perceptions of personal causality. The Heiders also raised three sons during this period: Karl, who became an anthropologist; John, a clinical psychologist; and Stephan, a physicist. Then, in 1947, now more than 50 years old and still an Assistant Professor, Heider made another academic change, moving to the University of Kansas in Lawrence, Kansas.

This appointment was at the instigation of Roger Barker, one of the founders of environmental or ecological psychology. Barker was trained at Stanford University and completed a 2-year postdoctoral position with Kurt Lewin while Lewin was at the Iowa Child Welfare Research Station (later renamed the Institute of Child Behavior and Development, closed in 1974). Barker was asked to chair the Department of Psychology at the University of Kansas, which like many other educational institutions was growing at the completion of World War II. Barker brought with him a group of other Gestalt psychologists, including Martin Scheerer, trained at the University of Hamburg; Herbert Wright, who also worked with Lewin in Iowa; and Heider. Heider remained in Lawrence, Kansas for the remainder of his life.

While at Kansas, Heider (1958) completed his groundbreaking book on social perception and social cognition, *The Psychology of Interpersonal Relations* (PIR). Chapters of PIR had been available earlier in mimeographed form but were known to only a few psychologists. The book was completed with the considerable aid of Beatrice Wright, who provided order to Heider's thoughts. A number of awards followed, including the Distinguished Scientific Contribution from the American Psychological Association.

Heider's subsequent enormous influence is all the more remarkable in view of the fact that it is largely based on this single, nonempirical publication. Furthermore, he worked at a rather unknown institution, without research assistants and little funding, with almost the total absence of doctoral students, and the book was published when he was 62 years old – only 7 years from retirement in 1965. For the most part, he was removed from the mainstream of American psychology.

Fritz Heider died in Lawrence, Kansas, on 2 January 1988 at the age of 92. He was a gentle man with a sly twinkle in his eyes, shy and introspective, with a love of art and literature and a wide-ranging intellectual curiosity. Among other personal descriptors, he was tall and thin; spoke with a soft, heavily accented voice; was modest and unpretentious; and exhibited little care about the material world around him, as opposed to the psychological world that dominated his thoughts.

Scientific Contributions

Heider applied the laws of the perception of physical objects and events developed by Gestalt psychologists to the perception of persons and their actions. Two conceptual contributions guided by this unification were presented in PIR, known as balance theory and attribution theory. These areas of thought were dominant in social psychology and related fields for two decades, 1960–80, and remain current. In addition and of lesser influence was his folk psychology approach to scientific thinking and methodology, which was displayed in his analysis of balance and attribution.

Balance Theory

Gestaltists contended that there is a tendency toward simplicity in the perceptual system such that simple structures are preferred. For example, faces are perceived as symmetrical although that is not exactly the case; and even when a circular form is not quite closed, it is nonetheless perceived as a circle. Furthermore, parts of a system become organized and the groupings form a simple structure in an uncontrollable and inevitable manner. For example, two similar objects in close proximity to one another are joined to form a unit, as in the example of ** ##. In the perceptual field, particular arrangements are imposed.

Heider reasoned that object configurations, including social objects, could be classified into those that are in a balanced or imbalanced state. In social perception, balanced and harmonious configurations are preferred for they represent 'good' figures or simple structures. In determining the balance of a social structure, the sentiment and unit relations between the elements play a role. Sentiment relations are attitudinal or evaluative and are either positive ('like,' 'approve') or negative ('dislike,' 'disapprove'). Unit relations refer to belonging and, like sentiments, can either be positive ('similar,' 'close,' 'belongs to') or negative ('dissimilar,' 'far from,' 'does not belong to'). Heider drew upon Wertheimer's grouping principles of similarity, proximity, and covariation when formulating his ideas about unit determination. Furthermore, everyday concepts such as 'liking' and 'belongs to' formed the heart of his scientific method of mining folk psychology for the development of a scientific psychology of interpersonal relationships.

In a two-person system, if 'a' likes 'b' while 'b' likes 'a' (sentiment relations), then the system is in balance. But if 'a' likes 'b' while 'b' does not like 'a,' then there is disequilibrium; imbalance exists and there is a force toward change in the direction of balance. There is a simple mathematical rule determining balance: if the multiplication of the relations results in a positive sign, there is balance; a negative result indicates imbalance. Balance in this two-person system can be brought about by changing one's attitude toward the other, misperceiving the sentiment of the other, altering the attitude of the other, and the like. However, not all balanced systems are pleasant or sought. For example, if 'a' and 'b' dislike one another, then the system is in balance (since the multiplication of two negatives result in a positive sign) but is less satisfying than when 'a' and 'b' like one another.

Configurations with three entities, such as those involving two persons and an object, are more complex. If, for example,

'a' likes 'b' as well as object x (e.g., the elected president), then if 'b' does not like x, the situation is imbalanced and a force will be created to bring the system into a state of equilibrium by, for example, a change in one's attitude toward 'b' or toward x. In Heider's manner of integrating everyday observations, literary examples, and scientific analysis, he noted that many literary tragedies make use of balance principles (e.g., Romeo loves Juliet, Juliet loves Romeo, Juliet loves and obeys her parents but they do not accept Romeo). An example of 'latent' imbalance that contributed to the dramatic tension in Ibsen's *Wild Duck* occurs when a scrupulous husband loves his wife who, unbeknownst to him, has engaged in a dishonest act for his benefit.

Balance principles have been extended to larger number of elements and widely applied in the study of interpersonal relations, attitude change, social cognition, and other area of research. It was reported, for example, that allied coalitions before and during World War II could be predicted with the use of balance theory. In addition, a variety of cognitive consistency theories and associated ideas, including the widely recognized concept of cognitive dissonance, are closely related to Heider's notions of balance.

Balance theory provided a distinct approach to motivation because force toward change is derived from the configuration of cognitive elements rather than from psychogenic or viscerogenic need states, which Lewin and others deemed necessary for motivated action. In accordance with Gestalt principles, for Heider the dynamics of action arise out of the entire pattern of a complex structure. This documented an essential position of Gestalt psychology, namely, the whole is other than (or different from) the sum of the parts.

Attribution Theory

Causal attributions, or beliefs regarding the causes of events, were a second major focus of PIR. Attribution theory was even more impactful on the field of psychology than were Heider's beliefs about balance and played a major role in the history of social psychology.

In his analysis of causal inferences, Heider applied his causal theory of thing perception to the perception of persons, while recognizing that persons, being agents with intentions, are more complex than inanimate objects. Hence, in addition to determining when a person is the cause of an event, the perceiver needs to understand or draw inferences about the mind of that individual. As in thing perception, the perceiver is confronted with proximal stimuli and draws inferences about more fundamental distal causes. In precursory research, Heider and Simmel showed participants three moving objects on a screen (a large and small triangle and a circle). Interpretations of the film were usually made in terms of interactions between persons with feelings, with impacts perceived as fights generated by jealousy, joint movements as evidence of liking and 'belonging together,' and so on. Perceived causality thus organized perceptions and eliminated the distinction between the physical and a person.

The motivational instigator for causal attributions is the assumption that individuals desire to understand and to master their environment. This belief is in part derived from Buddhist philosophy as well as from functionalism in that understanding the causes of events is adaptive for future behavior. For example, if one's car does not start, then knowledge regarding the cause (shortage of gas, damaged battery) is sought and causal beliefs determine future behavior. Thus, attribution theory is included within the study of cognitive functionalism.

For Heider, causal beliefs, which answer 'why' questions, are elicited by physical events such as the unexpected appearance of water on the floor or a crack in the ceiling; by outcomes that apply to the self, such as failing an exam or being rejected for marriage; and by events and outcomes that refer to others, including another person failing an exam or being rejected for marriage. However, attribution search tends to be restricted to unexpected, negative, and/or important events inasmuch as causal understanding requires cognitive work.

In his analysis of causal inferences, Heider made use of some principles from balance theory. For example, individuals tend to attribute success to themselves and failure to the external environment. This has been labeled a 'hedonic bias' that maximizes positive affect and self-regard. Inasmuch as most individuals feel positively about themselves, ascribing positive outcomes to the self (a positive unit) and negative outcomes to external factors (a negative unit) results in a balanced system and therefore this bias may be a result of cognitive rather than (in addition to) motivational mechanisms.

In addition and in accordance with Heider's interpretation of thing perception, observers tend to ascribe events to the disposition of the actor rather than to the 'pull' of the environment. For example, in the situation where Jim hits John, the cause is likely to be perceived as Jim's aggressive disposition rather than to a provocation by John. The overestimation of person causality and the underestimation of environmental effects have been labeled 'the fundamental attribution error.' According to Heider, in a manner similar to the perception of a house rather than the rays of the sun, this perceptual error is fueled by the tendency to locate causality in enduring distal causes (the disposition and/or intent of the person) rather than to changing environmental stimuli (the proximal cause or media that provides information about distal causes).

Contemporary Attribution-Related Research

As previously indicated, attribution theory was a dominant conception in social psychology from approximately 1960–80. However, its influence did not end there. It remains a presence in social psychology and has made deep inroads in the fields of clinical psychology, motivation and emotion, cognitive psychology, educational psychology, personality, and political psychology. It is almost impossible to discuss interpersonal relationships without recognizing the concepts of balance and/or attribution. When assessing the contemporary impact of Heider, it must be recognized that his influence is now carried by more contemporary figures who interpreted and elaborated his ideas, while adding their own insights. Among the main contributors one generation removed from Heider are Harold Kelley, who made Heider's thoughts known through an influential book review and because of his analysis of covariation information as depicted in the 'Kelley cube'; Edward Jones, who conducted the initial studies regarding dispositional

biasing; and Bernard Weiner, who brought attribution principles to the study of achievement motivation and emotion. These three were among the authors of the book: *Attribution: Perceiving the Causes of Behavior* (1972), which helped lift attribution to a prominent role in psychology. More recently, other researchers two generations removed from Heider have, in turn, replaced these figures as leaders in their field.

What follows is a sampling of some of the attribution-related research areas that can be traced to the foundation laid by Heider. Rather than assessing the validity of the various hypotheses that have been suggested and tested, these research directions are merely presented here to show some of the intellectual activity stimulated by Heider's thoughts.

Clinical Psychology

There is substantial research examining whether causal ascriptions are precursors to depression and/or follow depression onset. Some have contended that when the causes of aversive outcomes are perceived as unchanging, unchangeable, and/or implicate the self, then a state of learned helplessness or hopelessness is experienced and depression may follow. That is, depression is caused by dysfunctional causal reasoning.

In addition to the adverse consequences of self-related attributions, inferences about the causes of symptoms displayed by others can contribute to the course of mental illness. Critical and hostile emotional expression from caregivers, spawned by the causal belief that the other is responsible for his or her illness, increases the recidivism rates of schizophrenics as well as depressives. Mutual blaming for negative events also contributes to (and follows from) dissolving marriages by giving rise to resentment, anger, and discord.

Aggression and Prejudice

A number of different expressions of aggression have been subject to attribution analyses. Some types of child abuse, wife battering, and marital hostility can be traced to the aggressor ascribing intentional misbehavior to the other ("She purposively made me a bad meal."). In general, aggressive individuals tend to overattribute intentionality to others when experiencing a negative outcome. Hostility also is displayed toward the stigmatized when those individuals are perceived to be responsible for their plights (e.g., obese because of overeating), as opposed to being nonresponsible victims (e.g., obese because of a thyroid problem). Prejudice also is a product of (or may elicit) different attributions for in-group and out-group members. For example, aggression by an out-group member tends to be perceived as controllable by others and intentional, thus producing further out-group derogation.

Coping

Following a negative life stressor, such as rape, unwanted pregnancy, or illness, there often is a search for causality ("Why me?"). Some individuals ascribe the aversive event or outcome to their character ("I am too impulsive."), whereas others place fault on a particular behavior ("I was at the wrong place at the wrong time."). These contrasting causal beliefs elicit different coping mechanisms. The more adaptive behavioral blame results in active coping, whereas the less adaptive characterological blame, which implicates stable aspects of the self, gives rise to dysfunctional reactions. In general, coping depends on the taxonomic placement of the perceived cause of a problem into three fundamental categories: due to the person or the environment (labeled causal locus); an enduring or temporary cause (causal stability); and a controllable or not controllable cause (which in good part determines responsibility and blame). Self-attributions to internal, stable, and uncontrollable causes particularly elicit poor coping strategies.

Motivation and Emotion

Attributions for achievement success and failure have important consequences on subsequent striving. Guided by a can/try distinction articulated by Heider, it has been documented that attributions for failure to lack of aptitude (an internal, stable, and uncontrollable cause) are particularly debilitating, in contrast to ascriptions to insufficient effort (internal, unstable, and controllable causality), which promote positive motivation. In a similar manner, the belief or mindset that ability is changeable is more adaptive than the belief that one's ability level is a fixed entity.

Reactions of others also are guided by inferences about the causes of success and failure. Nonattainment of a goal because of lack of aptitude elicits sympathy and help from others, whereas failure due to low effort gives rise to anger and antisocial reactions. Furthermore, self-ascription of success to high aptitude elicits negative reactions from others, who regard the successful person as arrogant. On the other hand, self-ascription of success to effort or luck results in others labeling this individual as modest.

Appraisal approaches to emotion have documented that what one thinks, particularly about causes, determines how one feels. For example, guilt is typically preceded by the belief that one "could and should have done otherwise," whereas shame often follows from the inference that the causes of personal failure cannot be changed and mark one as different from others. Anger, regret, gratitude, and many other emotions follow from specific causal ascriptions.

Cognitive Psychology and Psycholinguistics

Many researchers have examined the antecedents of causal beliefs, ranging from individual differences in traits such as optimism – pessimism to the role of covariation information and rules regarding necessary versus sufficient causality. Of course, not all attempts to understand the contents and process of causal inferences can be traced back to Heider, inasmuch as phenomenal causality has been a long-standing interest of philosophers. Nonetheless, some of the proposals and thoughts do find their origin in Heider's thinking. For example, linguists have pointed out that verb forms affect causal reasoning. The phrase "I admire him" results in causality residing in the admired person, whereas the action sequence "Mary dominates Joan" places causality in the person committing the act. Those interested in gender issues have contended that journalists influence lay causal inferences when they state: "The flirtatious woman was raped by him," as

opposed to "He raped the flirtatious woman," with the former more promoting blame of the victim.

Political Psychology

Causal ascriptions are central components of political ideology and differ along the person – environment continuum pointed out by Heider. Conservatives, or those on the right of the political spectrum, tend to place causality for problems such as poverty on the person (laziness, lack of thrift, addicted, and so on) while maintaining it is not the fault of the government. In this manner, their causal beliefs are consistent with their desire to maintain the status quo and justify the negative stance of Republicans toward social welfare. On the other hand, liberals, or those on the left of the political spectrum, tend to see the causes of problems as residing in the environment (the government does not provide education or jobs, low wages). These attributions are consistent with their desire to change society and justify the positive attitude toward social welfare held by Liberals. In sum, causal beliefs are linked with broader political identifications.

Summary

It is evident from this very brief and selective article that Heider's ideas about perceptions of causality, represented in what is known as attribution theory, have a broad influence in psychology. In combination with balance theory, Heider left a flourishing psychological legacy.

Scientific Method

The sources of Heider's ideas were largely observational and literary. He relied on 'thought experiments' in which interpersonal situations were imagined and altered in a systematic manner (e.g., assume Romeo does not like Juliet, or that Juliet does not care about her parents). The psychological consequences of these new cognitive patterns were then inferred and related to configuration balance. This method may seem atavistic given the movement of psychology toward an experimental science but it proved fruitful for Heider, who advocated conceptual explication rather than empirical research.

For Heider, the psychology of social relations requires an understanding of the concepts used by the layperson, who was regarded as a naïve Newtonian relying on conceptual or logical inferences. The understanding of lay concepts does not necessitate, according to Heider, empirical methods. For example, if one leaves the house and turns right at the block corners, then that individual will arrive back home and this conclusion is not in need of empirical proof. Heider used this method of analysis to explicate concepts such as want, wish, benefit, harm, suffer, ought, can, try, and so on. He contended that reconstruction of the meaning of these terms reveals basic principles of social cognition. That is, the general conceptual structure embedded in everyday language provides the framework for describing psychological phenomena. In sum, Heider believed that a scientific psychology could be built on the common-sense psychology and language of everyday life and that a nonempirical conceptual analysis of everyday concepts provides psychologists with the methodology for the building of a social psychology of interpersonal relationships. Because of these beliefs and his mental experiments, Heider was labeled a 'naïve psychologist.' However, he did not advocate the elimination of empirical methods as opposed to an increase in conceptual treatments. And since his theoretical analysis embraced abstract principles, it provided laws that a layperson could not articulate. Thus, the 'naïve' characterization is not correct (although it contains a kernel of truth).

This contribution of Heider, however, met with little success, even among attribution and balance theorists. There were many reasons for the aversion of social psychologists to an analysis of common sense, ranging from the irrational (fear of not being regarded as a scientific endeavor) to the rational (the belief that science must develop its own language systems). However, the common-sense label applied to attribution theory played an important role in the history of attribution thinking. Attribution theory took hold after cognitive dissonance ruled psychology in the 1960s. At the core of this theory was the belief expressed by Leon Festinger, most responsible for this conception, that theory should contradict common sense. Subsequently, the waning of attribution theory toward the end of the 1980s coincided with (was caused by) a refocus on unconscious determinants of behavior and the growth of neuropsychology in cognition. Thus, attribution theory was framed within two contrasting Zeitgeists.

Abstract

This article outlines the life and career of Hermann von Helmholtz in order to illuminate his influence on the nascent social sciences, above all on psychology. In doing so, it indicates how Helmholtz's major contribution to developing the Law of Conservation of Energy helped inspire social and economic thinkers to conceive of individual human bodies and society at large in terms of energy. Moreover, it indicates how his work on determining the velocity of nerve impulses, other measuring work in physiological acoustics and optics, and his leading role in the nativist–empiricist controversy, contributed to the rise of experimental psychology. It stresses his use of instruments and the measuring process in making the sciences (here especially physiology and psychology) ever more rigorous disciplines. Finally, it indicates how his work and name were admired (if not always emulated) by several young luminaries of social science around the turn of the twentieth century.

Life

Hermann Ludwig Ferdinand von Helmholtz was born in Potsdam, Germany on 31 August 1821. His father taught humanistic subjects at the local gymnasium and he encouraged Hermann's keen interests in music and the arts, in enjoying nature, and in philosophy. At the gymnasium Helmholtz distinguished himself in every subject of study. Although his great intellectual love was physics, his father persuaded him that there was little call for professional physicists and that, in any case, he could not afford to send him to university. Helmholtz thus enrolled (in 1838) at the Royal Medical-Surgical Frederick-William Institute (Königliches medicinisch-chirurgisches Friedrich-Wilhelms-Institut) in Berlin, the Prussian military medical school, which provided full support to its students in exchange for 8 years of military service.

After graduating in 1842 and serving for a year as an intern at Berlin's Charité hospital, Helmholtz served nearly 5 years (1843–48) in Potsdam as an army doctor. The position afforded him much free time and he spent it conducting research in physiology and physics, publishing several papers in physiology and a seminal essay in physics. Then in 1848–49, he served as assistant to his former teacher Johannes Müller, a leading comparative anatomist and physiologist, and as an anatomy instructor in Berlin, before being given an early release from his remaining military obligations in order to begin an academic career as Extraordinary Professor of Physiology at the University of Königsberg. His career was launched.

While at Königsberg, Helmholtz invented the ophthalmoscope (1850). It soon revolutionized ophthalmology by allowing doctors to examine the living human retina, and thus to diagnose the eye far more thoroughly and treat it for disease. It also led to Helmholtz's becoming a full professor, boosting his reputation among the Prussian educational authorities, and giving him a pan-European reputation. So too did his related work in creating an ophthalmometer and in developing a theory of the eye's accommodation. In 1855, he transferred to the University of Bonn, where he spent the next 3 years as Professor of Anatomy and Physiology. Then, in 1858, he accepted Baden's offer to become Professor of Physiology at the University of Heidelberg. A year after his arrival there, his wife Olga died, leaving him a widower with two young children to raise. He was soon remarried, to Anna von Mohl (with whom he had three children), who made their home into a social center of Heidelberg intellectual life. The university built him (as part of a larger science complex) a new institute of physiology; he served as the university's Prorector (1862–63); and, more generally, became one of its stellar figures during what became its golden era.

With the establishment of the German Reich in 1871, the Prussian authorities were determined to reacquire Helmholtz as part of their effort to turn the University of Berlin into the centerpiece of German academic life. Helmholtz now became Professor of Physics at Berlin and Director of its Physics Institute. Prussia built him an entirely new physics building, the largest such in Germany; and his institute became a mecca for German and foreign students alike. In going to Berlin, Helmholtz also left physiology almost entirely and devoted himself almost exclusively to physics. From time to time he also pursued work in other areas: independently inventing non-Euclidean geometry; conducting pathbreaking work in chemical thermodynamics and theoretical chemistry; and conducting work in theoretical meteorology. His contributions to each of these areas were considered foundational. Still, it was mostly in the area of physics, in particular theoretical physics, that he worked from the late 1860s until his death in 1894. In Berlin, Helmholtz became an even more prominent figure in German academic and intellectual life than in Heidelberg. Since the early 1850s, he had regularly been called upon to give popular lectures on science, which he continued to do throughout Germany and in Britain. Thanks to his wife Anna, his home became one of Berlin's leading *salons*. He regularly served the Prussian and Reich governments as a representative at national and international scientific meetings, and in 1883 the German Kaiser ennobled him for his services. Four years later, he was appointed the founding President of the Imperial Institute of Physics and Technology (Physikalisch-Technische Reichsanstalt, PTR), a nonacademic government institute devoted to research in physics and technology, including the setting of physical standards and testing. He spent the last 7 years of his life directing the PTR and pursuing theoretical physics. He died in Berlin on 8 September 1894.

Scientific Contributions Pertinent to the Social Sciences

Helmholtz produced well over 150 original scientific papers, which were reproduced in his three-volume *Scientific Papers* (*Wissenschaftliche Abhandlungen*, 1882–1895); a three-part *Handbook of physiological Optics* (*Handbuch der physiologischen Optik*, 1856–1867) that analyzed and synthesized the results of physiological optics; a pathbreaking treatise on the scientific foundations and aspects of music, *On the Sensations of Tone as a Physiological Basis for the Theory of Music* (*Die Lehre von den Tonempfindungen, als physiologische Grundlage der Theorie der Musik*, 1863); and a two-volume collection of some 25 popular and philosophical essays (*Vorträge und Reden*, fifth edn., 1903) on various aspects of science. The hallmarks of Helmholtz's efforts in science included a gift for generalizing and synthesizing results; using the methods or results of one discipline to advance another; showing the importance of instrumentation and measurement for advancing science and doing so in a rigorous manner; turning philosophical problems into scientifically amenable questions; analyzing the epistemological foundations of science; relating science and art to one another; and popularizing science. Although Helmholtz was himself not a social scientist – the English term itself being an anachronism during much of his active career – several highly selective aspects of his work in physics and physiology merit attention for their pertinence to the social sciences, above all psychology.

The Conservation of Energy and Socioeconomic Thought

In the mid-1840s, Helmholtz and several other young physiologists (Carl Ludwig, Emil du Bois-Reymond, and Ernst Brücke) sought to establish an 'organic physics,' i.e., to explain life processes exclusively on the basis of the laws of physics and chemistry, thereby ridding physiology of the vague notion of 'life force' (*Lebenskraft*). Helmholtz centered his early scientific efforts on the problem of heat and its mechanical equivalent. In 1847, he published his epoch-making concept of the principle of conservation of force. Although he was only one of several scientists in the 1840s who conceived of the idea of force conservation in physical or physiological systems, his presentation offered by far the most systematic, mathematical, and general account to date, thereby helping to connect various disparate branches of physics. The work was part of his larger program of providing a fully mechanical interpretation of nature, organic as well as inorganic, though Helmholtz neither then nor later, maintained that human beings, whom he believed to possess free will, could be understood solely in material and mechanical terms.

During the 1850s and the 1860s several British physicists (especially William Thomson) transformed Helmholtz's principle of force conservation into that of 'energy conservation' and thus into the First Law of Thermodynamics. This new energy-based physics and the associated concept of 'work,' generally inspired a number of economic and social thinkers in the second half of the century. Thanks in good measure to Helmholtz's work, physical scientists and social thinkers alike now unequivocally recognized the impossibility of perpetual motion. Social and economic thinkers began to see both the individual human body and socioeconomic systems in general, in terms of individual or societal energy production, consumption, transformation, and output. Helmholtz helped give economists a greater sense of the importance of the conservation and general circulation of energy. His work in thermodynamics also helped deepen understanding of the human body as a mechanical system, a human motor. The new thermodynamic viewpoint helped give new meaning to the terms 'work,' 'labor,' and 'value.'

Nerve–Impulse Measurements

Helmholtz's work on the propagation velocity of the nerve impulse spoke directly (if unintentionally) to the interests of an emerging set of experimental psychologists. In 1849–50, Helmholtz conducted a series of experiments on the propagation velocity in frogs, demonstrating that the impulse was propagated at a finite and measurable velocity. He and others saw that the reflex nerve action could also be measured in humans, and that there was a small, noninstantaneous (finite) time interval between human thought and bodily response.

As a result, the traditional mind–body problem took on a new shape and a vigorous program of stimulus–response studies in physiological psychology began. Helmholtz's work provided (by implication) a measure of a subject's reaction time to sensory stimulation, e.g., to visual or auditory cues, to voluntary movements, and to the association of ideas. Wilhelm Wundt and others built on Helmholtz's work by constructing methods for measuring the time intervals in thought processes. Helmholtz's work, along with Ernst Heinrich Weber's and Gustav Theodor Fechner's psychophysical results (including the latter's stimulus–response law and his *Elements of Psychophysics* (*Elemente der Psychophik*, 1860)); Adolph Hirsch's chronometric studies on 'physiological time'; Wundt's physiological psychology; the work of Franciscus Cornelius Donders and Johan Jacob de Jaagers on the speed of thought, among others, marked important milestones in the emergence of experimental psychology as a separate discipline in the 1850s and 1860s. To be sure, through the last third of the nineteenth century the term 'experimental psychology' assumed a wide variety of meanings; yet it also (if not mainly) meant that some psychological phenomena could be measured quantitatively and so become the subject of laboratory research.

Physiological Acoustics and Optics

Beyond neurophysiology proper, Helmholtz's importance to the emergence of experimental psychology lay generally in his work in physiological acoustics and optics, especially in his two great books, the *Handbook* and *On the Sensations of Tone*. These two masterpieces became the standard reference works – and, for many, points of scientific departure and philosophical debate – for psychologists and others. Both had a similar structure: they first gave analyses of the physical aspects of their respective subjects, physiological optics and acoustics; then came the physiological analyses of the respective sensations of light and sound; and, finally, arguments for the importance of the psychological factor in mentally integrating sensations into experienced perceptions or sounds. In particular, Helmholtz believed that 'unconscious inferences' transformed the physical and physiological sensations received by the sensory organs and

associated nervous systems into perceptions. From birth onwards, he argued, the individual learned through empirical experience that certain types of behavior produced certain types of responses, which, in the course of time, the mind transformed into unconscious inferences, and from there into actions.

Helmholtz's work in physiological acoustics and optics began with his theory (borrowed from Müller) of specific sense (or nerve) energies. Müller had maintained that the stimulation occurring in each type of sensory organ was responsible for a specific sensory experience; each type of sensory nervous system was qualitatively different from the others. Helmholtz extended this theory for vision by claiming, as had Thomas Young long before him, that there were three sets of optical nerve fibers, each of which provided its own specific nerve energy that corresponded to the primary colors. Similarly, he extended Müller's theory for hearing by maintaining there were several thousand specific auditory energies. He presented his so-called resonance theory of hearing in *On the Sensations of Tone*, arguing that the ear is a set of resonators that analyzes homogeneous sounds into their components. Although he thought that the sensory processes of hearing and seeing were in good part mechanical ones, he did not think that sensations were copies, let alone mirror images, of the external world; rather, they were the 'signs' of it. Although his theory of specific energies was modified or rejected by some, it came to constitute part of the foundations of experimental psychology.

The Nativist–Empiricist Controversy

Helmholtz was not simply one of the two principal antagonists (Ewald Hering being the other) in the nativist–empiricist controversy over the proper foundations of vision research. He coined the very labels of these two fundamental positions and did much to shape the controversy between himself and Hering and their respective followers. Although their differences were many, the two sides mainly disagreed on whether the eye possessed and required a mind to see. The controversy began in the 1860s and lasted until the 1920s; indeed, in several ways it has continued down to the present.

In the *Handbook*, Helmholtz labeled Hering and his followers 'nativists,' since they claimed that spatial perception was innate to newborns. By contrast, he called himself and his followers 'empiricists,' since they claimed that spatial perception was an acquired phenomenon, one that each individual gradually learns through daily experience and which requires the mediation of unconscious inferences. The two sides also disagreed about the receptor mechanisms affecting color vision and about explanations for contrast phenomena, adaptation, optical illusions, eye movements, the constancy of color, retinal correspondence, and so on.

The controversy helped shape the intellectual substance and disciplinary formation of physiology and psychology. Experimentally minded psychologists like Carl Stumpf, Georg Elias Müller, and Franz Brentano opposed the empiricist view insofar as it employed unconscious inferences and so harkened back to psychology's roots in philosophy. On the other hand, nativism's stress on the biological foundation and explanation of perception threatened to replace psychology with physiology. Yet nativism also emphasized the role of phenomenological experience, and this appealed greatly to a number of experimental psychologists, including Stumpf, Hermann Ebbinghaus, Oswald Külpe, Erich Jaensch, and David Katz.

The Broad Impact of Helmholtz's Work on Psychology and Beyond

Unlike Fechner and Wundt, Helmholtz had no desire to create a new, institutionally independent discipline of psychology. His contributions and overall importance to the discipline came largely (and indirectly) from his work in physiology and physics and from his general prestige. His contributions to the 'New Psychology' – a broad, hardly uniform movement that first arose in Germany between 1860 and 1910 and was associated with such names as Wundt, Ebbinghaus, Külpe, Stumpf, Hugo Münsterberg, and others – consisted largely in the observational and experimental study of, and speculation about, sensations and perceptions. The New Psychology in good measure replaced the older philosophical psychology and in so doing adopted, adapted, or extended many of its methods and results from sensory physiology and psychophysics, not least those introduced by Helmholtz.

Helmholtz's work deeply influenced and must be seen against the emergence and course of the New Psychology. During the 1860s and 1870s, a number of psychologists aligned themselves with (sensory) physiology and it was during these decades that Helmholtz had his greatest impact on the field. For example, Wundt, who was Helmholtz's assistant at Heidelberg, shared Helmholtz's empiricist theory of perception, and Helmholtz later drew on Wundt's work on vision for his *Handbook* and supported him professionally. As advocates of psychology as an experimental discipline, they were allies. Yet there were also differences between the two: Wundt later rejected Helmholtz's mechanistic approach to sensation, the two men had a priority dispute concerning the theory of unconscious inferences, and Helmholtz criticized several of Wundt's views. The young Ebbinghaus was similarly influenced and supported by Helmholtz, whose work on the measurement of the velocity of nerve impulse served as a starting point for Ebbinghaus' famous work on measuring memory. Helmholtz was also one of Ebbinghaus' examiners for the right to teach at Berlin, where Ebbinghaus lectured in psychology (1880–94) and where Helmholtz supported him in other ways.

In 1890, when Ebbinghaus and Arthur König founded the *Zeitschrift für Psychologie und Physiologie der Sinnesorgane*, they included Helmholtz on their editorial board, perhaps more to honor him as a venerable figure than as an active practitioner of physiological psychology. The new journal played a leading role and constituted an important milestone in physiological psychology. Yet the discipline of psychology was itself changing. As it gradually separated from physiology during the last third of the century, a number of its practitioners (especially after 1920) gradually abandoned its elementalist, sensory-based approach in favor of the phenomenalistic approach of the Gestalt psychologists, who rejected Helmholtz's mechanistic approach to psychology and, like the nativists, his theory of perception. In short, from the 1890s psychology moved away from Helmholtz's views and gained a new sense of intellectual and institutional autonomy.

Helmholtz also had a strong impact on other young psychologists, two of whom warrant special mention. As a medical student and young medical researcher, Sigmund Freud became especially enamored with the program of 'organic physics.' (He studied principally with Brücke in Vienna and once hoped to study with Helmholtz in Berlin, though nothing came of this.) The young Freud sought to link neuropsychological to physiological phenomena, and his early psychological language is the language of physiology (e.g., that of 'energy'). He called Helmholtz 'one of my idols.'

Likewise the young William James had intended to study with Helmholtz, but never did so. He called Helmholtz 'immortal' and said that he was "perhaps the first scientific genius now [in 1868] above ground." Helmholtz's work and views on physiological psychology constituted an important source for James. As a young scientist, he assiduously studied Helmholtz's *Handbook*, *On the Sensations of Tone*, and the popular and philosophical essays. Helmholtz was one of the most-frequently cited authorities in James's *Principles of Psychology*. Although James often cited him positively (especially as a source of empirical evidence) he rejected Helmholtz's notion of unconscious inference and his sensation-based theory of perception; and he found Helmholtz's mechanistic and mathematical predilections in science alien to his own. James wrote of the *Handbook*: "Can I find fault with a book which, on the whole, I imagine to be one of the four or five greatest monuments of human genius in the scientific line? If truth impels I must fain try, and take the risks. It seems to me that Helmholtz's genius moves most securely when it keeps close to particular facts."

Beyond psychology, Helmholtz also affected several of the future leaders of the next generation of social science in ways that are perhaps impossible to pin down precisely. The young Franz Boas had originally intended to become a physicist and to study with Helmholtz but he never did, soon turning away from physics and toward geography before settling on anthropology. (Helmholtz did, however, serve as one of Boas's examiners when he, successfully, sought to obtain the right to teach at the University of Berlin.) The young Wilhelm Dilthey was a frequenter visitor to the Helmholtz home in Berlin. Although Dilthey's holistic and dynamic theory of consciousness stood in sharp contrast to Helmholtz's 'sensationalist' approach, he studied Helmholtz's writings carefully; considered Helmholtz's popular scientific essays as the best such set that had ever appeared in German; engaged him in friendly discussions over their philosophical differences; and graced his own *Introduction to the Human Sciences* (*Einleitung in die Geisteswissenschaften*, 1883) with an opening quote from Helmholtz.

By the 1920s Helmholtz's substantive achievements and outlook had undoubtedly lost some of their attraction for some psychologists. Nonetheless, for many in Germany and abroad, Helmholtz still stood, as he did for Max Weber in 'Science as a Vocation' (1919), as a model scientific researcher. Moreover, in developing his general views and analyses of the sociology of music, Weber turned to Helmholtz's work in the physiological foundations of music. In *On the Sensations of Tone*, Helmholtz had stressed the historical nature of musical development and he distinguished between natural laws and aesthetics. His book effectively laid the basis for the sociology of music. Weber used Helmholtz's book as one of his principal scientific analyses of music and music history guides in his own *The Rational and Sociological Foundations of Music* (*Die rationale und soziologischen Grundlagen der Musik*, 1921).

Helmholtz's general impact on the rise of psychology (and other areas of the social sciences) from the mid-nineteenth century onwards was thus broad and fundamental. Edwin G. Boring, in the second edition of his monumental *A History of Experimental Psychology* (1950), ranked Helmholtz, along with Darwin, James, and Freud, as one of the four most important figures in the history of psychology.

Helping Intergroup Relations

Abstract

The article begins with research on help giving across racial boundaries, and continues to consider the different motivations that underlie the giving of help to the out-group (e.g., secure rewarding relations with the out-group or repairing the in-group's damaged image). The article continues to describe the effects of group members' self-categorizations on their willingness to help the out-group. It continues to the intergroup helping as status relations model, which rests on social identity theory that analyzes how groups create, maintain, or challenge existing status relations between them through the readiness to give, seek, or receive help to and from the out-group.

Since the 1960s, the phenomenon of helping has been a growing area of social psychological research (Penner et al., 2005). Much of this research centered on interpersonal helping and sought to answer the questions of *who*, *whom*, *when*, and *why* people help (Dovidio et al., 2006). The question of 'who helps' centered on developmental processes and personality traits that characterize the helpful individual. The question of 'whom' one helps centered on the effects of the identity of the person in need on the readiness to help him or her. And the question of 'when help' takes place focused on situational determinants of helping. Research on the helper's thoughts and feelings as factors that explain the giving of help is the focus of the 'why help' question. A parallel line of research centered on the recipient of help. It sought to uncover the variables and processes that predict and explain people's decision to seek help and their reactions to receiving it (Nadler, in press). This research has demonstrated that being helped is a double-edge sword. On the positive side, receiving help often alleviates difficulties and is seen by the recipient as a reflection of the helper's genuine care. On the other hand, dependency on others conflicts with the deeply ingrained value of self-reliance and may result in loss of prestige in the eyes of others and be detrimental to the recipient's self-esteem. Under these conditions, people often prefer to avoid seeking help or receiving needed help (Nadler, 2012).

The present article on *intergroup helping relations* departs from this traditional emphasis on interpersonal helping. It considers the variables that affect, and the psychological processes that explain, why and when people are willing to stretch a helping hand across the in-group boundary. The article begins with the research on *cross-racial help giving*, moves to consider the *motivations* that explain giving to an in-group or out-group, and continues to research on the role of *social identity* concerns in the giving, seeking, and receiving of help across group boundaries.

Cross-Racial Helping

Early research on intergroup helping focused on the readiness of White Americans to assist a White or an African-American. This research was driven by the concern that not helping a Black person constitutes the White bystander's expression of subtle racial prejudice. The decision of a White American to help an African-American reflects two opposing psychological tendencies. While prejudicial attitudes may inhibit the readiness to help, the norm against displaying such blatant discrimination will encourage help giving regardless of the needy's group affiliation. One manner in which people solve the conflict between prejudicial tendencies toward discriminatory nonhelping and the normative sanctions against expressing them is 'aversive racism' (Dovidio and Gaertner, 2004). This concept suggests that prejudices will be expressed when the costs of expressing them are relatively low and will not be expressed when these costs are relatively high. The aversive racist "discriminates primarily when features of the situation allow him or her to maintain a positive (that is, nonprejudiced) view of the self" (Hodson et al., 2010: p. 120). Applied to the context of cross-racial helping, this suggests that if nonhelping can be attributed to external circumstances rather than to the helper's prejudicial tendencies, the costs of refusing help are relatively low and discriminatory nonhelping is more likely.

This idea has received considerable empirical support. An early study found that when White participants had been under the impression that other bystanders are present, they discriminated against African-Americans by not helping them more than when they had thought that only they and the victim were present (Gaertner and Dovidio, 1977). What accounts for this finding is that when others are present, responsibility for intervention is distributed among all bystanders present, thereby lowering the cost of nonintervention (Latané and Darley, 1970). Two literature reviews of cross-racial help giving, published 25 years apart, have similarly noted that cross-racial helping is dominated by the phenomenon of aversive racism. The first concluded that a White helper helps Blacks and Whites equally only when the interaction between them is a face-to-face interaction (Crosby et al., 1980). This is because the cost of discrimination in a face-to-face interaction is higher than in an impersonal interaction. The second review indicates that discriminatory nonhelping was likely only when not helping could be rationalized by the helpers (e.g., help involved high risk) (Saucier et al., 2005). Finally, consistent

with the logic of aversive racism, White individuals who had failed to help a Black person defended against the negative implications of this discriminatory nonhelping by assessing the event as being less of an emergency than when they had failed to help a White person (Kunstman and Plant, 2008).

Although this research has focused on racial relations in American society, its implications extend more generally to help giving by advantaged to disadvantaged or stigmatized group. The findings suggest that advantaged groups will express their prejudices toward stigmatized groups by not helping them only when external rationalizations decrease the costs of a blatant discriminatory nonhelping. This principle will predict the readiness of the majority to assist a stigmatized group within society (e.g., AIDS victims) and the willingness of rich nations in the Western world to assist poorer, and often stigmatized, nations in the developing world.

Motivations for Cross-Group Helping

Giving help across group boundaries is multicausal. It is often driven by the helper's genuine desire to assist members of disadvantaged or persecuted out-groups. The example of gentiles who had rescued Jews in Nazi-occupied Europe is a shining example of such genuine altruism (Oliner and Oliner, 1988). But, the motivation for cross-group helping may be less noble. It may reflect in-group members' desire for rewards such as gaining a reputation of generosity for their group. In this section we consider the multicausal nature of intergroup helping.

Empathy for the Other's Need? Giving to In-Group versus Out-Group Members

The motivational mechanisms that drive help to out-group members are different from those driving help giving to in-group members. People perceive others in their group as similar to them, and this interpersonal similarity is an antecedent of feelings of empathy with the other's plight, which in turn drives giving help to them (Stotland, 1969). In comparison, giving to others from the out-group is based on cost–reward considerations; it is driven by the liking that one feels for the person in need and a concomitant assessment of the degree to which a future relationship with him or her would be personally rewarding (Stürmer and Snyder, 2009). Consistent with this logic, the personal attractiveness of the person in need predicted helping directed toward an out-group member more than it did help toward an in-group member (Stürmer et al., 2005), and empathy with the needy's plight predicted readiness to help an in-group member more than it did an out-group member (Stürmer et al., 2006). In support of the role of empathy as driving help giving to in-group members, Penner and Finkelstein (1998) reported that dispositional empathy predicted volunteering for AIDS victims among homosexual men, but not among heterosexual women.

A similar conclusion concerning the different motivational paths that determine giving to in-group and out-group members comes from theory and research on the principles that underlie social interactions in close and distant relational systems. Clark and Mills (1993) have distinguished between communal and exchange relations. In communal relations giving is determined by the other's need, and in exchange relations it is dependent on rewards that one had previously received from the person in need. A similar analysis of relations systems indicates that it is only in emotionally significant groups (e.g., family), labeled as communal sharing relational systems, that people give to others according to their need and not because of other considerations (e.g., equal sharing between all group members) (Fiske, 1991). Although the three distinctions (i.e., in-group vs out-group, communal vs exchange relations, and communal sharing vs other relational systems) do not overlap, they convey a similar message regarding the motivational underpinnings of giving to an in-group or to an out-group member. In closer and psychologically significant relationships that are more common within the group, people give on the basis of empathy with others' need. In relations that are more distant and formal and less psychologically significant – attributes that are more characteristic of relations with out-groups – the considerations that dominate are more instrumental (e.g., whether or not one had received similar rewards) and unrelated to empathy for the other's need.

Helping as a Mechanism of Image Repair: Strategic Helping

Because helping out-group members is more diagnostic of the helper's generosity than helping in-group members, giving to the out-group is more common when it is driven by the in-group members' desire to gain a reputation of generosity for the in-group. This motivation to achieve positive reputation through out-group helping – a form of strategic help giving – is likely to be higher when in-group members experience a threat to their group's reputation or prestige (van Leeuwen and Tauber, 2009). In support of this prediction, Dutch students who had read about the disintegration of Dutch national identity (i.e., high threat to national prestige) were later more supportive of the suggestion that the Netherlands should assist the victims of the 2004 tsunami in Asia than Dutch participants whose national reputation had not been threatened (van Leeuwen, 2007). The greater readiness to assist the out-group was particularly pronounced in an area central to Dutch national identity (i.e., managing water resources; van Leeuwen, 2007: Study 2). In another experimental demonstration of strategic help giving, compared to a no-threat control condition, Scottish participants whose group image had been threatened by being told that the English view Scots as mean gave more to an out-group than to the in-group (i.e., a Welsh and a Scottish organization, respectively) (Hopkins et al., 2007).

The research reviewed in the preceding sections addressed helping relations between 'real groups.' These were racial groups in the USA, or Dutch and Scottish national groups. The focus was on giving to another collective of individuals that made up a distinctly different group. In the remainder of this article, the dominant concept will be people's social identity. This shifts the focus from the 'real group' to the 'psychological group' and puts the limelight of theory and research on individual group members' feelings and cognitions associated with their group membership.

The Social Identity Perspective on Intergroup Helping

The Psychological Group: The Social Identity Perspective

Early social psychological research on intergroup relations has focused on relations between two, or more, *real groups* made up of congregations of individuals. The social identity perspective, introduced in the 1970s, asserts that an important anchor of people's self-concept is the group(s) to which they belong, and that when group affiliation is salient, an interaction with an out-group member is experienced as an intergroup interaction even when it is an interpersonal interaction (Turner and Reynolds, 2001). The social identity perspective consists of two lines of research and theory: self-categorization and social identity theories (Turner et al., 1987; Tajfel, 1982, respectively). *Self-categorization theory* elaborates the cognitive mechanisms that cause people to categorize themselves in terms of a particular social group. It proposes that such self-categorizations are malleable. While people are affiliated with numerous groups (e.g., citizen, student, football fan), situational conditions cause one affiliation to be more salient than others and to drive social behavior. In the context of helping, research has examined how processes of self-categorization affect in-group members' willingness to assist members of the out-group. *Social identity theory* has focused on the comparative element in intergroup relations. It asserts that group members are motivated to enhance the value of their in-group relative to the out-group because this enhances their own self-concept. Intergroup helping research anchored in social identity theory has centered on the way in which giving, seeking, and receiving help affects and is affected by intergroup status hierarchy.

Self-Categorization and Intergroup Helping

People's readiness to intervene on behalf of a stranger is affected by the intentions and attitudes of fellow in-group members. Participants who had watched a violent clip on CCTV were more likely to express, privately, intentions to intervene to help a stranger if the in-group members had publically indicated that they would do so and less likely to intervene if the in-group members had indicated that they would not. The public expressions of the out-group members had no effects on participants' intentions to intervene (Levine et al., 2002). The attitudes that other in-group members hold about the out-group also affect people's readiness to intervene across group boundaries. White participants who had been informed that fellow in-group members hold positive attitudes toward African-Americans were more helpful toward them than those who had not received similar information (Sechrist and Milford, 2007). Together these findings demonstrate that only the behavioral intentions and attitudes of other in-group members affect readiness to help across group boundaries.

An experimental investigation of the helper's self-categorization on his or her readiness to help an in-group and out-group person in need used the context of the rivalry between British supporters of different football clubs (Levine et al., 2005). The first experiment examined the hypothesis that when the identity of the in-group is salient, people would be ready to help only other in-group members. To induce a salient in-group identity, supporters of Manchester United had been asked to write a short essay on the importance for them of being a supporter. In a second phase, as they were leaving the room, they encountered a person in an apparent need for assistance. In the in-group condition the person was wearing a shirt with a Manchester United insignia, in the out-group condition his shirt had an insignia of the rival Liverpool club, and in the control condition his shirt had no insignia. The findings indicate that more participants stopped to help in the in-group than in the out-group or control conditions. Thus, increasing the salience of in-group membership lowers the readiness to help across group boundaries.

How can this discriminatory nonhelping be overcome? One way, suggested by self-categorization research, is the induction of a common group identity that unites the in-group and the out-group under an overarching identity, while allowing the two groups to maintain their separate identities (Gaertner and Dovidio, 2000). Thus, for example, if professors of psychology and professors of economics are induced to think about themselves as 'social science professors,' they are encouraged to use a broad category of representation that includes both the in-group and the out-group under the same overarching identity. Consistent with research showing the beneficial effects of common identity on attitudes toward the out-group, it was expected that the induction of common identity will lower discriminatory nonhelping (Levine et al., 2005: Exp. 2). The experimental context was the same as the one used in the first experiment. To induce common identity, participants, fans of Manchester United, had been asked to write about the importance of being a 'lover of football.' This manipulation created a common identity of 'football lovers' that united the separate identities of supporters of Manchester United and Liverpool under the broader category of 'lovers of football.' Under these conditions, the number of participants who intervened to assist a member of the out-group was the same as those who intervened to assist a member of the in-group, and higher than the number of those who intervened to assist a person in the control group. Similar findings are reported in other studies. White students who had been induced to view Black students as fellow team members, working on a common task, complied with their requests more than those who viewed them as individual Black students (Nier et al., 2001). Finally, Dovidio et al. (1997) obtained similar findings with ad hoc groups created in the laboratory. This replication is of particular importance because obtaining the same results with groups who have no prior history increases the internal validity of this phenomenon.

A real-world illustration of the ameliorative effects of common group identity on intergroup helping comes from research on individuals who rescued Jews during the World War II. By risking their own and their families' lives, these individuals demonstrated extreme altruism toward an out-group (i.e., Jews). In their research on the 'altruistic personality,' Oliner and Oliner (1988) compared a large group of rescuers to a comparable group of nonrescuers. Of special relevance for the present discussion of the effects of common group identity on out-group helping is the finding that rescuers had higher 'extensivity' scores than nonrescuers. Extensivity denotes people's "propensity toward inclusiveness with respect to the diversity of individuals and groups to whom one will

assume obligations" (Oliner and Oliner, 1992: p. 370). Consistent with the view of extensivity as a general personal disposition, rescuers were also found to be more likely than nonrescuers to have positive feelings toward other out-groups like Turks and Gypsies (Oliner, 2004). The meaning of extensivity is close to that of common group identity. It means that the person views the in-group and the out-groups as sharing an overarching and inclusive identity of human beings.

Another illustration of the effects of common identity on intervening in behalf of the out-group during extreme circumstances is Reicher et al.'s (2006) analysis of the saving of Bulgarian Jews from Nazi deportation in 1941. Based on an analysis of pronouncements made by the Bulgarian leadership, Reicher et al. conclude that a key reason for this rescue was that Bulgarian leaders emphasized that Bulgarian Jews share a common identity with non-Jewish Bulgarians (Reicher et al., 2006). Todor Polakov, a Bulgarian parliamentarian of the time, is quoted as saying, "Bulgarian Jews … speak Bulgarian … they sing Bulgarian songs and tell Bulgarian stories…" (Reicher et al., 2006: p. 58). Finally, recent research has substantiated the links between 'extensivity' and readiness to help the out-groups in more mundane daily interactions as well (Einolf, 2010). High scorers on an 'extensivity' scale built especially for this purpose evidenced equal readiness to help family members and strangers, whereas low scorers exhibited greater readiness to help family members and friends than strangers.

This discussion of self-categorization and intergroup helping has focused on cognitive mechanisms that affect the representations of the out-group and the in-group, but has not attended to the status relations that exist between these groups before and after the helping interaction. Yet many, if not all, intergroup relations occur between unequal groups, i.e., high- and low-status groups. With the aid of social identity theory, the next section analyzes intergroup helping between unequal groups.

Social Identity Processes: Helping Relations between Unequal Groups

Providing to others implies relative strength and resourcefulness, whereas being dependent on their help marks relative weakness and inferiority (Nadler, in press). In evolutionary theory, 'costly signaling' theory holds that organisms incur short-term losses in order to advertise their fitness as mates and allies (Zahavi and Zahavi, 1997). Giving to others constitutes a 'costly signal.' For example, by feeding genetically unrelated chicks, birds engage in wasteful short-term behavior that establishes their longer-term desirability as mating partners (e.g., McDonald et al., 2008). In human groups, people gain status and prestige by giving to others and lose it when they habitually depend on others' assistance (Blau, 1963; Flynn, 2003). Because generosity is linked to increased intragroup status, individuals often compete on who is more generous ('competitive altruism'; van Vugt and van Lange, 2006). From the recipient's perspective, being dependent on the help of others is associated with lower status. Consequently, people in need often refrain from seeking needed help and respond negatively to its receipt (Nadler and Halabi, in press).

Intergroup relations are also characterized by links between giving and higher status on the one hand, and dependency and lower status on the other. In his seminal essay "The Gift," Marcel Mauss (1925) described the custom of Potlatch, common in tribal societies of the Pacific Northwest, where a clan leader who is motivated to signal the clan's superiority gives excessive gifts to other clan leaders. Similarly, in the Melanesian Islands, the more lavish the gift given by the family of the deceased to other families, the higher its status (Smith and Bleige-Bird, 2000). In his classic essay *Democracy in America*, Alexis de Tocqueville remarked that members of the ruling class maintain their dominance by assisting disadvantaged groups. He wrote that receiving such assistance is "servitude of the regular, quiet and gentle kind" (de Tocqueville, 1835/1956: p. 303).

These observations amplify the fact that intergroup helping often occurs within the context of structural inequality. The intergroup helping as status relations model (IHSR, Nadler, 2002) proposes that intergroup helping relations between structurally unequal groups depend on (1) structural characteristics of the intergroup hierarchy, (2) the autonomy or dependency orientation of the help, and (3) characteristics of individual group members.

Regarding *structural characteristics*, social identity theory suggests that a status hierarchy can be structurally secure or insecure (Tajfel and Turner, 1979). The security or insecurity of the status hierarchy is determined by whether or not it is viewed as stable and/or legitimate. In a secure hierarchy, inequality is viewed as stable and/or legitimate. In insecure hierarchy, it is viewed as unstable and/or illegitimate. When status hierarchy is secure, neither the high- nor the low-status group is motivated to change the unequal status quo. When the hierarchy is insecure, members of the low-status group who perceive an opportunity to change their disadvantaged position are said to be motivated to move toward greater equality.

Gender relations offer an illustrative example of secure and insecure status hierarchies. In past centuries, the superiority of men over women was considered as both legitimate and stable. In more recent times such inequality is regarded as illegitimate and in need of change. The IHSR proposes that when the status hierarchy is secure, the advantaged group is expected to cater to the needs of the disadvantaged in return for the latter's gratitude, loyalty, and legitimization of the existing inequality from which the high-status group benefits. When the status hierarchy is insecure, dependency on the high-status group is inconsistent with the low-status group's desire for equality. Under these conditions, members of the low-status group are expected to reject help from the high-status group.

Regarding characteristics of the help, its *autonomy or dependency orientation* determines the dynamics of helping relations between structurally unequal groups. *Dependency-oriented help* consists of full solutions and *autonomy-oriented* assistance consists of tools with which the needy can solve the problem on their own (Nadler, 1998). Dependency-oriented help underscores the recipient's reliance on the helper, whereas autonomy-oriented help allows the recipient to maintain perceptions of self-reliance. Therefore, in secure hierarchies where dependency of the low-status group is consensual, help is likely to be dependency-oriented, whereas

in insecure hierarchies, members of the low-status groups who strive for equality are expected to be receptive only to autonomy-oriented assistance. Finally, *group members' characteristics*, such as in-group identification, are also expected to affect these helping dynamics. These hypotheses were examined in research on low-status group members' readiness to seek and receive help from the high-status out-group, and the high-status group's readiness to help members of the low-status out-group.

Help Seeking and Receiving: The Case of the Low-Status Group

Compared to African-Americans who had not received help, those who had been assisted by a White American suffered a decrease in competence-related self-esteem (Schneider et al., 1996). In a different context, Israeli Arabs (i.e., a disadvantaged group in Israeli society) had more negative reactions to help from an Israeli Jew than to help from an Israeli Arab (Halabi et al., 2011). Although these studies had not measured or manipulated the perceived security of the status hierarchy, it seems likely that in both societies, African-Americans and Israeli Arabs viewed their group's relatively lower social status as illegitimate and in need of change. Therefore, being dependent on the higher-status group was threatening to the social identity of the disadvantaged group in both of the above-mentioned societal settings. A more direct assessment of the role of the security of structural inequality indicates that when members of a low-status group had been induced to view status relations as unstable, they were less receptive to help from the high-status group than when inequality was perceived as stable. Importantly, this was true with both ad hoc, experimentally created groups (Nadler and Halabi, 2006: Exp. 1) and real-world low- and high-status groups (i.e., Israeli Arabs and Israeli Jews, respectively) (Nadler and Halabi, 2006: Exp. 2). In the same vein, the more Israeli Arabs viewed status relations with the advantaged group of Israeli Jews as unstable, the more suspicious they were of offers for help from the latter (Halabi et al., 2012). Regarding the role of individual characteristics, Arab Israelis characterized as high in-group identifiers reacted more negatively to help from an Israeli Jew than low identifiers (Nadler and Halabi, 2006: Exp. 3).

A final experiment in this research program assessed the combined effects of (1) security of structural inequality, (2) group members' characteristics, and (3) help characteristics on the readiness of members of a low-status group to seek help from the high-status group (Nadler and Halabi, 2006: Exp. 4). Participants were high school students who could seek needed help from a student in a prestigious high school in their region. Half of the participants had, or had not, been induced to identify with their school, and had been told that the achievement gap between their school and the prestigious school had either narrowed or remained the same over the past 10 years (i.e., *unstable vs stable hierarchy*, respectively). The findings indicate that the participants who had been induced to identify with their school and believed that the achievement gap between the schools is narrowing (i.e., unstable hierarchy) were unwilling to seek dependency-oriented help from a member of the high-status group. This finding illustrates the joint effects of *social structure*, the *kind of help*, and the *person in need* on low-status group members' receptivity to help, as predicted by the IHSR.

Giving by the High- to the Low-Status Group: Defensive Helping

When the advantaged position of the high-status group is threatened, its members may defend against this threat by negative means such as arresting the forward movement of the low status (Ellemers, 2002). They defend against the threat by the more positive means of giving the low-status group much dependency-oriented help, thereby underscoring its dependence and relative inferiority. Such helping, intended to defend against incoming threats to the advantaged group's position, was labeled 'defensive helping' (Nadler et al., 2009). In support of this rationale, veteran Canadians who had been told that new immigrants to Canada present an economic threat to veteran Canadian citizens recommended giving new immigrants dependency-oriented help in the form of financial assistance more than autonomy-oriented help in the form of teaching them new working skills (Jackson and Esses, 2000). Similarly, Australians who had been informed that status relations between veteran Australians and newcomers to Australia are unstable (i.e., high threat) recommended less autonomy-oriented help to newcomers to Australia than to veteran Australians (Cunningham and Platow, 2007). The defensive nature of such help in maintaining the existing unequal status quo is highlighted by its links with the belief that social inequality is necessary and just (i.e., social dominance orientation (SDO); Sidanius and Pratto, 1999). In fact, defensive helping is more characteristic of high-SDO people than low-SDO people. In both Canadian (Jackson and Esses, 2000; study 2) and Israeli societies (Halabi et al., 2008), high-SDO scorers in the advantaged group (i.e., veteran Canadians and Israeli Jews, respectively) gave less autonomy-oriented help to members of the low-status group (i.e., newcomers to Canada and Israeli Arabs, respectively).

Self-categorization processes shape the phenomenon of defensive helping. When a common identity had been induced by telling participants from a high-status school that their own and the lower-status school share the common identity of schools that represent the same region, they did not react to the threatening information that the low-status school is closing the achievement gap by giving much dependency-oriented help (Nadler et al., 2009: Exp. 3). Instead, under these conditions of common identity, students from the high-status group gave predominantly autonomy-oriented help to students from the low-status group who had been described as closing the achievement gap with them. These findings indicate that categorization processes determine the meaning of 'threatening' information and the consequent kind of help giving. When the out-group shares no commonality with the in-group, intergroup reality is construed as a win–lose reality. The advancement of the out-group is perceived as undermining the in-group's social position. These perceptions give rise to defensive helping intended to ward off the threat to social identity. When the two groups share a common identity, however, intergroup reality is no longer experienced as a win–lose situation, and the other's progress does not pose a threat to the in-group identity. Rather, it is regarded as evidence that

the low-status group has the potential to move forward, and autonomy-oriented help is dispensed to bring about greater intergroup equality.

Conclusions and Implications

The common view suggests that we care for, and are cared for by, those who are similar and psychologically close to us. The findings that similarity breeds empathy reinforce this view and suggest that helping relations typically occur within group boundaries. The present article, however, indicates that this is not always the case. Under certain conditions, people take risks and sacrifice their resources in offering a helping hand across group boundaries. Thus, for example, when members of disadvantaged groups (e.g., White Americans) cannot avoid responsibility to help a distressed individual from the disadvantaged group (e.g., Black Americans), they help in-group and out-group members equally. Also, when people view the in-group and the out-group as possessing a common identity of shared humanity, they take great risks to save members of stigmatized groups from mortal danger (e.g., rescuers of Jews in Nazi-occupied Europe).

Intergroup helping relations are multicausal. Giving to the out-group can be driven by self-serving motivations. People may assist an out-group in order to enhance or repair the reputation of their group and/or to change or maintain an existing social hierarchy between unequal groups. In secure status hierarchies, the unidirectional downward flow of dependency-oriented help institutionalizes the unequal status quo. In insecure hierarchies, the exchange of autonomy-oriented assistance builds a ladder of social change toward greater equality. Self-categorization processes shape these dynamics of intergroup helping. When the intergroup boundary is clear and the separateness of the two groups is salient, intergroup helping relations between unequal groups are viewed from a competitive zero-sum perspective. Under these conditions, the advantaged group engages in defensive helping in the form of dependency-oriented help to maintain its relative superiority. When the disadvantaged and advantaged groups, however, share a broader common identity, a perspective of intergroup equality dominates, and intergroup helping takes the form of empowering the disadvantaged group toward forward movement.

The findings and processes discussed here have important implications. They enrich our understanding of basic dynamics of intergroup and helping relations. On the more applied level, the findings and their conceptualization are relevant to numerous real-world contexts such as efforts by advantaged groups to promote self-reliance among the members of disadvantaged groups. These processes are relevant to contexts in which rival groups seek to build a base of cooperation between them, or when richer nations build assistance programs to help poorer nations. In all these contexts, intergroup helping relations are multicausal and can have positive or negative consequences for the helper and the recipient. The key question concerns the mechanisms whereby intergroup helping is a vehicle to promote values of cooperation, mutual respect, and equality, rather than to perpetuate a competitive, win–lose perspective based on social inequality.

Abstract

Patients with hemispatial neglect, a neurobehavioral deficit that manifests after a lesion that usually affects the right hemisphere, fail to process or attend to information appearing on the contralateral side of space. This deficit can arise in multiple modalities (visual, auditory, and somatosensory) and can adversely affect eye and hand movements. In addition to describing the phenomenon and its anatomical concomitant, the underlying mechanisms giving rise to this deficit are explored. The advent of cutting-edge neuroimaging and the recent development of new assessment and rehabilitation methods have also offered novel insights into the disorder and these are summarized here, too.

The Term 'Hemispatial Neglect'

One of the most dramatic deficits in spatial perception and action is hemispatial neglect ('neglect' for short), a neurobehavioral disorder in which a patient is unable to acknowledge, report, or otherwise make explicit use of information falling in the visual hemispace contralateral to the lesion (Bartolomeo and Chokron, 2001; Harvey and Rossit, 2012; Kerkhoff and Schenk, 2012). Neglect occurs more commonly and with greater severity after right than left hemisphere lesions in humans (Suchan and Karnath, 2011) and this asymmetry is consistent with the differential involvement of the right hemisphere in processes of attention and spatial representation, as revealed in many recent neuroimaging studies (Chica et al., 2011; Ptak and Schnider, 2011). Because of this hemispheric asymmetry, in this review, we will refer to neglect as 'left-sided' and to 'contralesional' as a lesion to the right hemisphere.

The Phenomenon of Hemispatial Neglect

Neglect is not an uncommon disorder and every year about 3–5 million patients present with neglect after sustaining a stroke (Corbetta et al., 2005). Moreover, about a third of these patients manifest a chronic form of the impairment, which can persist for more than a year postonset (Karnath et al., 2011; Rengachary et al., 2011). Neglect can be greatly debilitating in everyday life; individuals may fail to notice objects on the left of a scene, may ignore words on the left of a page or food on the left of a plate, may drive their wheelchair into the side of a doorframe, and may dress and/or shave only one side of their body. Neglect can also interfere with rehabilitation efforts by adversely affecting mobility, discharge destination, length of hospital stay, meal preparation, and independence in self-care skills (Barer, 1990; Bernspang et al., 1987) and, understandably, then, neglect can affect the outcome of rehabilitation and long-term prognosis.

Neglect is not restricted to the visual domain; patients may not orient to contralateral auditory information, may not detect a contralateral somatosensory stimulus and may even ignore contralateral odors (for review, see Kerkhoff et al., 2012). Neglect is also not restricted to sensory input; patients with neglect may plan and even execute movements more poorly to the contralateral than ipsilateral side and this holds both for upper limb movements as well as for eye movements. The reduction in the speed and the precision of movements to the left appears not to be solely a downstream consequence of the sensory impairment and thus, problems in computing the parameters of contralateral movements is yet another manifestation of neglect.

The failure to process information on the contralateral side cannot be attributed to either a primary motor impairment or to a hemianopia; even when information is presented to the intact visual field of a neglect patient, information in the contralateral hemispace is still neglected. Patients may even show neglect in the absence of visual input; for example, as revealed in a particularly elegant and dramatic experiment, patients may ignore the left side of a scene constructed entirely in visual mental imagery (Bisiach and Luzzatti, 1978) and may fail to search the left of a dark room (Hornak, 1992). Finally, patients can be cued to process information on the contralesional side through verbal or other visual instructions although, left to their own devices, they tend not to orient contralesionally. Taken together, these findings all rule out a primary sensory deficit as being causally linked to neglect.

Aside from the general characteristics of neglect as set out above, the exact manifestation of neglect across patients is not monolithic. Thus, some patients demonstrate neglect for the contralesional side of the body (personal neglect as in dressing only one side of their body) but show no deficits on clinical tests requiring scanning across space (for example, on drawing or cancellation tasks). Other patients can show extrapersonal or allocentric neglect, where they fail to respond to external, contralesional stimuli, and when they do, the neglect can be for information appearing in near space (peripersonal neglect) or far space (or upper or lower space, see below). Neglect occurs most frequently along the horizontal plane although 'altitudinal neglect,' in which information appearing in the upper rather than lower portion of an array (or vice versa) is ignored, may also occur (Pitzalis et al., 2001). Neglect may also occur along the radial dimension although this pattern is thought to be related to the need for a motor response and is less commonly seen when perception alone is tested.

Finally, in some individuals, the severity of the neglect can be modulated by the nature of the information being processed; thus, the left side of items that 'belong' together or are connected perceptually is less subject to neglect than disconnected items (Behrmann et al., 1990; Tian et al., 2011; Ward et al., 1994). Whether different patterns of neglect are associated with different lesion sites is still controversial and this issue is discussed in greater detail in Section Different Forms of Neglect in Relation to Different Lesion Sites.

The Assessment and Diagnosis of Neglect

The diagnosis of neglect is generally rather straightforward – neglect is, in a standard manner, elicited in tasks in which the patient must either cross out items that appear randomly scattered on a piece of paper or must mark the midpoint of a single horizontal line and the neglect disorder can be elicited at the patient's bedside. Neglect is also typically observed when a patient is asked to draw or copy a simple picture such as a daisy or a clock and details on the contralesional side are generally omitted. A particularly popular test for hemispatial neglect, the Behavioral Inattention Test (Wilson et al., 1987), which consists of six subtests including drawing and line bisection, continues to be a measure of choice for many clinicians and researchers. The Birmingham University Cognitive Screen (BUCS; http://www.bucs.bham.ac.uk) is also useful and can be helpful in differentiating between different forms of neglect such as allocentric and/or egocentric neglect (Riddoch et al., 2010).

There have been other recent attempts to increase the sensitivity and reliability of assessment measures. The Sunnybrook Neglect Assessment Procedure, is the result of one such recent effort, and includes a small battery of tests that are quickly and easily administered and have high diagnostic differentiation (Leibovitch et al., 2012). Some bedside tests of hemispatial neglect, however, are still somewhat insensitive to subtle (but clinically relevant) forms of the disorder and considerable effort has been devoted to developing tools to address this issue. For example, the virtual reality lateralized attention test (Buxbaum et al., 2012) is an easy-to-administer computerized measure of hemispatial neglect that mimics the attentional demands of real-world tasks. In this test, participants name objects as they navigate (or are navigated) along a winding virtual path. Similarly, using virtual reality procedures, assessment techniques have been developed in which targets are placed at multiple locations and participants are required to locate the spatially disparate targets (Dvorkin et al., 2012). These latter, more dynamic, three-dimensional assessment tools offer a new approach, which may be valuable in identifying more subtle forms of the disorder and in tracking changes associated with interventions.

Underlying Mechanisms

A number of general interpretations have been advanced to account for the varied manifestations of neglect. For example, some have suggested that neglect arises from a deficit in orienting spatially to the contralesional side with a gradient of attention biasing attention to the ipsilateral side. Others have argued that the problem is one in which there is a rotation or translation of the egocentric frame of reference toward the ipsilesional side. Yet a third suggestion, the premotor theory of neglect, is that there is an imbalance between the spatial representations that control motor programs, and that this imbalance gives rise to an attentional deficit. Although described as alternatives, these differing interpretations may not be mutually exclusive and may refer to different aspects of a single deficit. What is clear at present is that, although they may diverge in detail, these explanations share a common perspective and that is that neglect is a higherorder, rather than sensory, spatial impairment.

One view of neglect, formalized by (Pouget and Driver, 2000) is that neglect reflects a partial loss or dysfunction of cells in the parietal cortex and other related neural areas. Because the number of neurons for representing information in different lateral positions is limited, damage to these neurons gives rise to a pathological gradient with a smooth decline for increasingly leftward locations and an off-center peak reflecting the peak activation on the ipsilateral side. Consistent with this idea, a spatial gradient has been incorporated into several neural network models that simulate neglect, and these theoretical models have successfully captured many aspects of neglect including extinction, performance on line-bisection and line cancellation tasks, and neglect dyslexia as manifest in various reading tasks (Mozer and Behrmann, 1990; Pouget and Sejnowski, 2001).

Alternatively, it has been argued that neglect behavior is best explained by the altered balance between the functioning of distributed default attentional cortical networks rather than by cell death, or structural damage, of specific regions. Recent studies investigating attentional control in neurologically intact individuals have demonstrated that attentional control is largely supported by two parallel networks, one dorsal and one ventral, each playing a specific role in attentional control (Corbetta and Shulman, 2011; Shomstein et al., 2010a,b; Vandenberghe et al., 2012). Corbetta and Shulman (2011) have argued that more ventral lesions to right parietal, temporal, and frontal cortices *directly* impair nonspatial functions (mediated by a ventral frontoparietal attention network) while also *indirectly* impacting the structurally intact more dorsal attentional network that is directly responsible for spatial attention. The fact that the behavioral gradient, described earlier, is known to be modulated by arousal and task instruction is then taken as further evidence that the underlying neural mechanisms are modulated by signals from other regions that are intact (areas within the dorsal network) rather than completely destroyed by structural damage. Perhaps related is the observation that neglect is accompanied by hypoperfusion (insufficient levels of oxygenation) of areas in the right angular and supramarginal gyrus and/or right superior temporal gyrus (Hillis et al., 2005; Khurshid et al., 2012), and that reperfusion, or rTMS, of these areas is associated with improvement of neglect (Cazzoli et al., 2010; Khurshid et al., 2012).

Lesion

As evident from the above discussion, much recent research has been concerned with demarcating the lesions that give rise to

neglect and the relationship between the lesions and the neural correlates that have been identified with attentional networks in nonneurological individuals in recent functional imaging studies. Traditionally, visual neglect has been associated with lesions of posterior parietal cortex but more recently, there has been increasing disagreement concerning the neural concomitant of the disorder.

Recent Lesion Mapping in Patients with Neglect

Recent studies exploiting high-resolution structural imaging, in tandem with voxel-based mapping and lesion overlap analyses, have confirmed the standard brain-behavior relationship, pinpointing the temporoparietal junction and the angular gyrus as the neural basis of neglect. Several other studies, however, have identified additional regions such as the intraparietal sulcus as being critical for neglect – a lesion to this region affects the reorientation of the spatial focus of attention and the ability to select between competing stimuli (Gillebert et al., 2011; Vandenberghe et al., 2012). Karnath and colleagues, for example, have reported that neglect may be associated with damage to more anterior areas, including the superior temporal gyrus and insula (Karnath and Rorden, 2012). Others have argued for the involvement of several other critical regions in addition to damage to posterior parietal regions, including, for example, the frontal eye fields and cingulate cortex. Yet others have proposed that the site of the lesion is tightly coupled to the type of neglect, with more dorsal lesions resulting in deficits of top-down guidance of attention and more ventral lesions resulting in a neglect deficit affecting bottom-up attentional guidance. Finally, much recent work exploiting diffusion tensor imaging to map white matter integrity in lesion patients has revealed that visual neglect can result from, and be correlated with, damage to frontoparietal connections in the right hemisphere, and that these white matter changes adversely affect large-scale cortical networks that are important for orientation of spatial attention, arousal, and spatial working memory (Bartolomeo et al., 2012; Karnath and Rorden, 2012; Urbanski et al., 2011).

Different Forms of Neglect in Relation to Different Lesion Sites

Many patients with left neglect following right hemisphere damage have neglect that manifests both egocentrically (i.e., show neglect with left defined with respect to the midline of coordinates centered on the body) and allocentrically (i.e., show neglect with left defined with respect to the midline of coordinates centered extrapersonally). In one recent study, roughly two thirds of individuals with neglect displayed both allocentric and egocentric neglect, while the remaining patients showed pure egocentric neglect. Consistent with the findings reported in Section Recent Lesion Mapping in Patients with Neglect above, the lesions in the inferior frontal gyrus, precentral gyrus, postcentral gyrus, superior temporal gyrus (STG), middle temporal gyrus (MTG), insula, and surrounding white matters were more frequent in the neglect group than in the control group. Of greater interest here is that there is a differentiation in lesion site depending on the pattern of neglect; thus, lesions in the right STG, MTG, lenticular nucleus, and the surrounding white matter were more frequent in the group displaying both allocentric and egocentric neglect than in those with pure egocentric neglect (Yue et al., 2012). The exact neural underpinnings of the different manifestations of neglect is still controversial, however. For example, Riddoch and colleagues have argued that egocentric neglect was associated with more anterior lesions, including the superior temporal gyrus, the supramarginal gyrus, and middle frontal gyrus whereas, allocentric neglect was linked to more posterior lesions, including the middle occipital and temporal gyri and the angular gyrus (Riddoch et al., 2010). Note, however, that Vallar and colleagues have alternately proposed that allocentric neglect is associated with more ventral, occipitotemporal lesions (Vallar et al., 2003).

It is also interesting that reperfusing specific areas has differential impact on different forms of neglect: for example, reperfusion of dorsal frontoparietal cortex is associated with improvement in viewer-centered (egocentric) neglect, whereas reperfusion of a more ventral temporooccipital cortex, is related to improvement in allocentric, stimulus-centered neglect (Cazzoli et al., 2010; Khurshid et al., 2012).

Implicit Visual Information Processing

One of the most provocative claims in the research on neglect is that, despite the loss of phenomenal awareness of the contralateral information, patients are able to process a considerable amount of contralateral information implicitly and this information can be used to guide their behavior (Driver and Vuilleumier, 2001). An early observation suggested that these patients 'knew' more than their overt responses suggested (Kinsbourne and Warrington, 1962). Thus, for centrally presented words, patients with neglect dyslexia often retained word length in their erroneous responses, for example, producing MILKMAN for MAILMAN. The influence of the unattended left-sided information has also been observed in other lexical tasks, in which patients with neglect produced faster responses to a stimulus in the right field when it had been preceded by a brief presentation of an associated word in the neglected left field (Ladavas et al., 1997a,b).

Other innovative paradigms have been developed to explore this issue in greater detail, allowing for the probing the integrity of more rudimentary perceptual processes on the neglected (contralesional) side. Specifically, studies have shown some degree of processing of the contralesional stimulus when it can be grouped with the ipsilesional stimulus on the basis of bottom-up factors such as color and proximity (Driver and Halligan, 1991), or by brightness or collinear edges (Gilchrist et al., 1996; Rorden et al., 1997). This is also true when the contralesional information is grouped with the right information by a global outline (Farah et al., 1993), and when the contralesional information forms the left side of an illusory contour (Kanizsa-type figure) of a partially occluded figure (Mattingley et al., 1997), or of any well-configured object or whole (Gilchrist et al., 1996; Humphreys and Riddoch, 1994).

Although the findings reported above are provocative and of great interest, many of the studies employed designs in which stimuli presented to the neglected field were associated with

stimuli presented on the right side of space by virtue of, for example, perceptual filling in, grouping by similarity, lexical relatedness, or semantic category. It remains possible, therefore, that the activation and processing of information on the neglected side occurs by virtue of the priming of the left-sided information by the intact right-sided information rather than being activated on its own merit (Boutsen and Humphreys, 2000; Brooks et al., 2005; Driver et al., 1992; Kumada and Humphreys, 2001; Mattingley et al., 1997; McGlinchey-Berroth, 1997). A recent study by Shomstein et al. (2010) employing semantically unrelated and task-irrelevant stimuli that avoids the possibility of priming information from the right to the left side, has nevertheless confirmed the processing of nonattended contralesional information. In this study, patients with left-sided neglect (and matched controls) judged whether successive complex checkerboard stimuli (targets), presented entirely to the intact right side of space, were the same or different. Concurrent with this demanding ipsilateral task, irrelevant distractor elements appeared on the unattended side and either changed or retained their perceptual grouping on successive displays, independently of changes in the ipsilesional, task-relevant, target. Changes in the grouping of the unattended task-irrelevant distractor produced congruency effects on the judgments of the ipsilateral attended targets to the same extent in neglect patients as in the control participants and this was true even in those patients with severe attentional deficits. These finding provide confirmatory evidence for the residual processing, at least to the level of perceptual grouping, of the neglected information. Much remains to be done to uncover the neural mechanisms that enable the processing of unattended information that is not available for overt report.

Perspectives on Rehabilitation

A diverse set of strategies has been adopted in studies designed to rehabilitate patients with neglect. While the intervention methods are numerous, there is not yet a single agreed-upon method that has proved to be the most effective. In a comprehensive literature review of cognitive rehabilitation following hemispatial neglect, Bowen and Lincoln examined the findings from 12 randomized controlled trials with 306 participants. Although the conclusion reached is that the overall effect of intervention was not statistically significant, cognitive rehabilitation did improve performance on some standardized neglect tests, including a reduction in the number of cancellation errors and an improvement in the ability to bisect the midpoint of a line. In a similar vein, an inclusive review of cognitive rehabilitation studies performed from 1998 to 2002 and then updated in 2005 (Cicerone et al., 2000, 2005) acknowledges the efficacy of cognitive rehabilitation, but also found that there is limited or insufficient evidence for the duration of treatment effects or relevance to everyday functioning (see also Rohling et al., 2009).

One of the most widely used rehabilitative methods, employed in clinical settings, is visual scanning or visual exploration therapy (VST or VET) in which patients are presented with an array of items and are asked to find an item embedded somewhere in the visual display. Of note is that this type of therapy is rather time-consuming with a reported minimum of 40 treatment sessions needed in order to achieve stable results (Antonucci et al., 1995; Kerkhoff, 1998). Empirical studies aimed at evaluating VST/VET's efficacy have yielded mixed results finding that, at worst, patients do not benefit from the method (Antonucci et al., 1995) or, at best, show very specific improvements (Kerkhoff, 1998).

It has been suggested that one of the central deficits in neglect is an orientation bias to the right, and therefore, several therapeutic techniques have been aimed at weakening the rightward bias and shifting the orientation bias centrally. Caloric vestibular stimulation in which iced water is introduced to the left ear and stimulates the vestibular apparatus has been shown to lead to a dramatic, albeit, short-term improvement in the disorder. This procedure has been shown to improve neglect-related disturbances of body perception, unawareness of hemiplegia, and postural imbalances, as well as the perception of the subjective straight ahead that is usually shifted to the right (Karnath, 1994; Rode et al., 1992, 1998). Vibration of the left neck muscles (which produces an afferent that is similar to twisting the trunk midline leftward) has also been shown to be successful (Johannsen et al., 2003; Schindler et al., 2002). Another approach to restoring interhemispheric imbalance that is currently being explored is rTMS and, although this is relatively new, some promising data are already available (see Cazzoli et al., 2010, for review).

Most recent rehabilitative efforts have been focused on prism adaptation as a technique showing potential for long-lasting effects. Patients wear glasses with lenses that shift visual information several degrees to the right (anywhere from 10° to 20°). When goggles are first placed on the patient, the patient performs motor actions, typically consisting of reaching out and touching a visual target that is placed randomly in right and left visual fields. As a consequence, patients will make erroneous reaches proportional to the degree of visual shift. If, however, patients are allowed to observe the last part of the action, they quickly learn to correct for the discrepancy. Following the adaptation period, the goggles are removed and patients are asked to make the same type of reaching movements again. Just as during the adaptation, patients make erroneous reaches only this time shifted in the opposite direction from the target (i.e., to the left of the actual target). Studies using this technique have shown that, following a brief (in some studies as short as 15 min) prism adaptation procedure, there is an increase in attentive behaviors toward the neglected side. Patients also showed increased exploratory behaviors toward the previously neglected side and this benefit persists even after the glasses have been removed (Ladavas et al., 2011; Serino et al., 2006, 2007, 2009; Turton et al., 2010). What sets this intervention apart from the previous attempts to alleviate unilateral neglect is that the observed amelioration generalizes across several different clinical measures, including wheelchair navigation, postural control, and neglect of mental imagery. In addition, the effects can persist for as long as 4 days (in rare cases 5 weeks) after a single adaptation procedure (Frassinetti et al., 2002; Pisella et al., 2002). The neural basis of the improvements remains poorly understood and may involve plasticity in some brain areas, although the parietal lobe is notoriously nonplastic

(Kolb and Cioe, 1998). It is also possible, however, that whatever change is observed may arise from involvement of other postural alterations (such as the shift of the viewer-midline more leftward).

Many other forms of treatment are also being explored. For example, in recognition of the fact that patients with neglect often have deficits in nonspatial forms of attention, too, some intervention approaches have focused on improving vigilance or sustained attention. One recent successful study of this type had patients monitoring long streams of novel visual scenes and, by virtue of this tonic and phasic alertness training, the researchers were able to demonstrate improvement in spatial as well as nonspatial forms of attention (Van Vleet and Degutis, 2012).

Concluding Remarks and Future Directions

As is clear from this review, hemispatial neglect is a heterogeneous and complicated disorder that defies simple explanation, and there remains a pressing need to understand what psychological and neural alterations give rise to this disorder. A further issue that requires additional investigation is the relationship of the spatial and nonspatial deficits in patients with neglect and their underlying neural correlates (Corbetta and Shulman, 2011). Much also remains to be determined regarding the underlying spatial map or frame of reference that defines neglect and whether the different manifestations of neglect arise from different underlying lesions and require different types of intervention.

An additional pressing issue concerns the fate of the neglected information; whether this information is processed normally and in a rich and detailed fashion but is somehow not available for conscious or explicit report continues to be hotly debated and highly controversial (Esterman et al., 2000). Promising studies using functional magnetic resonance imaging have shown differences in brain activation in the striate and extrastriate regions of the contralateral hemisphere for stimuli that have been extinguished compared with those that are reported (Driver and Vuilleumier, 2001; Marzi et al., 2000; Rees et al., 2000; Vuilleumier and Rafal, 2000) and further explication of the neural dynamics that support representations of nonattended information remains to be undertaken.

A final issue to resolve concerns the role of the parietal/temporal cortex in relation to other cortical regions that are involved in spatial processing. The parietal/temporal cortex does not have a monopoly on spatial processing and regions such as the frontal cortex and parahippocampal regions also contribute importantly to spatial representations. How these different areas work separately and/or together to give rise to our unitary visual experience remains unclear but neuropsychological studies with patients suffering from hemispatial neglect allow us to observe some of the representations and processes that ultimately contribute to our unified spatial experience. These findings together with those obtained from functional imaging studies with normal subjects, single-unit recordings from nonhuman primates and computational analyses continue to provide new insights into this perplexing disorder.

Abstract

Carl Gustav Hempel was a leading figure of the logicoempiricist movement, originating in the 1920s in Vienna and Berlin. He is particularly famous for his work on scientific explanation that led to the 'Hempel–Oppenheim model' of scientific explanation and his work on concept formation in empirical science. Hempel, furthermore, connected his methodological ideas with the thesis of the unity of science, according to which there holds the same methodology both in the natural and in the social sciences. In his later work, Hempel opened up to T. S. Kuhn's historic-pragmatic conception of science.

Carl Gustav Hempel was a leading figure of the logicoempiricist movement that dominated much of American philosophy in the second third of the twentieth century and has been a principal source of present day analytical philosophy. In the spirit of logical empiricism, Hempel aimed at a scientific philosophy with the principal objective to arrive at a purely logical methodology of the empirical sciences, including the social sciences. His most important contribution in this respect is what can be regarded as the first theory of scientific explanation (Salmon, 1989). This theory is referred to as 'the Hempel–Oppenheim model,' the 'covering-law model,' or the 'standard model of scientific explanation.' In his later years, Hempel gave up the idea of a purely logical (i.e., syntactical and/or semantical) 'rational reconstruction' or 'explication' of basic methodological concepts like explanation, confirmation, law of nature, probability, type, etc. Both the internal failure of this program and the influence of Thomas S. Kuhn caused Hempel to acknowledge for a satisfying reconstruction of methodological concepts also 'pragmatic' aspects of science in the sense of social and historical circumstances of its development.

Biography

Hempel was born on 8 January 1905, in Oranienburg (near Berlin, Germany). He studied mathematics, physics, and philosophy at the universities of Göttingen, Heidelberg, and Berlin from 1923 to 1929. After graduation (*Staatsexamen*) that qualified him to teach in secondary schools (*Gymnasien*), Hempel went to Vienna to study with Moritz Schlick and, particularly, Rudolf Carnap. Both, together with the mathematician Hans Hahn, the economist Otto Neurath, and others, had founded in 1923 the 'Vienna Circle' (*Wiener Kreis*), which was to become the nucleus of logical empiricism. After his return to Berlin in 1930, Hempel entered teacher's training and teaching and worked at the same time with Hans Reichenbach, head of the 'Berlin Group' of logical empiricism, on a philosophical dissertation on the concept of probability. After graduation in 1934, Hempel preferred to leave Nazi Germany and went to Brussels to assist Paul Oppenheim, a private scholar, in carrying out philosophical research that related principally to concept formation in empirical science. In 1937–38, Hempel worked for a year as research associate with Carnap in Chicago and again went back to Brussels until he found a post of instructor at City College, New York, in 1939. The academic year 1940–41 saw him at Queens College, New York, from where he went as associate professor to Yale in 1948. In 1955, Hempel became Stuart Professor of Philosophy at Princeton. After retirement at Princeton in 1973, he worked as university professor at Pittsburgh University from 1977 until 1985. He died at Princeton on 9 November 1997.

Major Contributions

Hempel has given important contributions to (1) the rational reconstruction of methodological concepts, particularly the concept of scientific explanation; (2) the 'universality thesis,' i.e., the thesis that the social sciences do not, and should not, use methods that are essentially different from the methods of empirical science; and (3) concept formation and taxonomy in empirical science.

Scientific Explanation

Hempel reconstructs scientific explanations of concrete events in nature, history, and society as arguments, i.e., as logical deductions containing as premises (*explanans*) at least one (general) scientific law L_1, as well as initial and boundary conditions C_r and as conclusion (*explanandum*) the statement E describing the event in question. We thus obtain the following model of 'deductive-nomological (D-N) explanation':

$L_1, L_2, \ldots, L_n$	the *explanans*
$C_1, C_2, \ldots, C_r$	[entails logically]
E	the *explanandum*

In case the *explanandum* contains essentially a statistical law (e.g., for all *x*: the probability of *G*, if *F* is given, equals *r* and as boundary condition that *F* is given for some *b*), the explanatory argument does not deliver a deduction of the *explanandum* statement E but rather gives inductive support for E, i.e., the *explanans* shows that E was to be expected with a certain degree *r* of probability. In simplified form (one statistical law, one

boundary condition), we thus obtain the following model of 'inductive-statistical (I-S) explanation':

$p(G, F) = r$	the *explanans*
$F(b)$	[lends inductive support of probability r to]
$G(b)$	the *explanandum*

In the case of I-S explanations, one must further assume that the *explanans* is maximally specified, i.e., the *explanans* must contain all available information that is possibly relevant for the explanation of the *explanandum* E. In other words, the *explanandum* must contain all pertinent statistical laws and those special facts that can be connected with the E event by statistical laws. I-S explanations thus relate to the body of scientific knowledge at a given time, i.e., they become 'epistemically relative.' The postulate of maximum specificity avoids the 'explanatory ambiguity,' i.e., the possibility to give acceptable I-S explanations based on true premises for mutually exclusive *explananda*.

In case one deduces as *explanandum* a general or a statistical law of lesser generality than the one(s) in the *explanandum* one obtains the reduction of a law or theory in the first case (e.g., explaining the law of free fall by means of the law of gravitation), and a deductive-statistical or D-S explanations of a statistical law by a more comprehensive statistical law in the second.

Originally, Hempel claimed the structural identity of explanation and prediction. Later he had to admit that, although every adequate explanation is (under pragmatically changed circumstances) also a prediction, not every adequate prediction yields also an adequate explanation, for symptoms are often adequate for a prediction but not for the corresponding explanation. So is, for example, a sudden fall of the barometer (together with suitable laws) sufficient for predicting a thunderstorm, but it does not explain it, since the fall of the barometer is not the cause of the thunderstorm, but rather a symptom of its arrival (Hempel, 1965).

Unity of Science

Hempel claims the methodological unity of empirical science. With respect to scientific explanation this amounts to a universality thesis of scientific explanation: There is no essential difference between explanations in the natural sciences and those in psychology, the social sciences, or history. Explanations in these fields likewise aim at showing that the event in question was to be expected on the basis of antecedent and boundary conditions and general laws. In history, those general laws are usually taken from psychology, sociology, economics, the natural sciences, etc. Hempel leaves the question open whether genuine historical laws exist. Normally, explanations in history and sociology fail to include an explicit statement of the laws they presuppose. This failure is due to the fact that those laws are part of folk psychology and seem to be tacitly taken for granted. Apart from that, it is difficult to formulate in a sufficiently exact way the underlying general assumptions about, e.g., the outbreak and course of revolutions. Furthermore, most of the regularities in the social sciences are statistical. Therefore, one can expect only explanation sketches in these fields.

The method of empathic understanding that is often claimed to distinguish the social from the natural sciences is neither sufficient nor necessary for explanations in these fields. It is not *sufficient*, because the individual act of understanding is only a heuristic device in order to suggest general psychological hypotheses that might subsequently serve as explanatory principles in the case under consideration. It is not *necessary*, because a historian might well be able to explain the deeds of a paranoiac historic personality by reference to the principles of abnormal psychology without being able to arrive at an emphatic understanding of such a personality.

Concept Formation in Empirical Science

Hempel's work on concept formation in empirical science originates in his early cooperation with Paul Oppenheim and consists basically in the application of principles of logical empiricism to the formation of scientific concepts (Hempel and Oppenheim, 1936). Hempel distinguishes (1) classificatory, (2) comparative, and (3) quantitative concepts. These distinctions normally characterize at the same time the historical development of a science from its initial descriptive 'natural history' stages to its mature theoretical stages. Classification divides a given set or class of objects (e.g., human beings) into subclasses (e.g., beings that suffer from certain mental disorders). Each of these subclasses is defined by means of a certain concept (e.g., schizophrenia) that represents the complex of characteristics essential for the membership in that subclass. Hempel speaks also of 'classificatory types.' The elements of these subclasses are those individuals to whom the respective concept applies (e.g., schizophrenics). The characteristics that form the defining concept are ascertainable fairly directly by observation. Classificatory concepts as well as scientific concepts in general have to fulfill two requirements. They have to (1) be objective and (2) have systematic import. Objectivity is attained first by using operational criteria and (often only partial) operational definitions in a large sense that includes observation as operational and second by eliminating criteria with valuation overtones. Scientific concepts have systematic import if they lend themselves to the formulation of general laws or theoretical principles. Classificatory concepts are a yes-or-no affair, i.e., a certain individual belongs to some subclass or not, whereas comparative concepts admit of more or less with respect to a certain trait (e.g., x is warmer than y with respect to cold–hot). They lead to (quasi) linear orderings as soon as one includes the relation of coincidence (e.g., x is equally warm as y). Hempel calls the extremes of such orderings 'ordering types.' The next step would consist in giving these linear orderings a metric and thus arriving at quantitative concepts (e.g., temperature).

For Hempel the 'ideal types' that have become popular in the social sciences since Max Weber are neither classificatory nor ordering types. Ideal types are interpretative or explanatory schemas that contain a set of empirical generalizations that establish subjectively meaningful connections between different aspects of some kind of phenomenon, e.g., purely rational economic behavior, a capitalist society, and a religious sect. Accordingly, ideal types must be reconstructed not as concepts but as theoretical systems that are intended to provide explanations and therefore must contain testable hypotheses. Despite their lack of clarity and precision, there

thus are also with respect to ideal types no essential methodological differences between psychology or the social sciences and the corresponding methods in the natural sciences (Hempel, 1952, 1967).

Influence, Impact, and Current Significance

Hempel's ideas constitute the mature form of logicoempiricist thinking (Fetzer, 2001). His work on scientific explanation 'stands out as the benchmark to which all subsequent studies of this topic must be referred' (Salmon, 1998, p. vii). His reconstruction of concept formation in empirical science has become a sort of standard for objective procedures of concept formation. It has greatly influenced subsequent editions of the *Diagnostic and Statistical Manual* of the American Psychiatric Association (Houts, 2001). His later work reflects the openness of logical empiricism to new developments in the philosophy of science (particularly T.S. Kuhn's work) that put a strong emphasis on the historical and sociological (pragmatic) factors of the development of science (Hempel, 1979, 2000; Wolters, 2003).

Abstract

Louis Henry, a French demographer, made significant contributions to the analysis and measurement of demographic phenomena and to population modeling, particularly in the area of fertility, where he focused on the physiological factors and the determinants of natural fertility. He is credited with developing the basic methods used today in historical demography, including family reconstitution.

Henry was born on 19 February 1911 and was 35 years old when he joined the newly created French Institut National d'Études Démographiques (INED) in 1946; he retired in 1973 and died on 30 December 1991. Most of his work was published under the auspices of INED, either in the journal *Population*, or in the Institute's monograph series. He was one of several retired artillery officers hired by INED because of their rigorous mathematical education at the national *Ecole Polytechnique*; others were Jean Bourgeois-Pichat and Sully Lederman, who would also leave their mark in the field, although they had no formal training in the social or historical sciences. Henry soon joined forces with Paul Vincent in the study of fertility, and this became his area of specialization. He made an early contribution to its measurement by inventing a new index, the parity progression ratio (Henry, 1953). This is defined as the proportion of women with a particular number of children, or parity, who have gone on to have another child, and is computed on the basis of the number of children ever born recorded at a particular age.

Henry intended to go beyond the mere measurement of phenomena, and undertook to decompose reproductive processes into their component factors, what later became known as the proximate determinants of fertility. He decided to study the 'physiological' level of fertility, that is, the fertility that would prevail among married women or couples in the absence of deliberate efforts to limit their number of births; this he called 'natural' fertility. In a contemporary population, however, contraception and abortion that are subject to human decisions are widespread, and it becomes difficult to investigate physiological factors. In his quest to find reliable data on populations where family limitation was not practiced, Henry studied records from the European past, at a time when the recording of vital events was complete and accurate. He first used a series of genealogies on the ruling classes of Geneva, going all the way to the sixteenth century (Henry, 1956); later he analyzed the parish records for a village of Normandy, Crulai, that had been extensively compiled by a local historian, Etienne Gautier (Gautier and Henry, 1958). The records for Geneva demonstrated the sharp contrast between the earliest marriage cohorts, where marital fertility by age seemed to be independent from age at marriage, and the later cohorts where the behavior of couples was clearly modified by the duration of their marriage and the number of children they had attained. It could be shown conclusively that the bourgeoisie of Geneva had adopted family limitation as early as the second half of the seventeenth century. In contrast until the end of the eighteenth century, Crulai, the first parish analyzed by the new method of family reconstitution that Henry had invented, showed the features of a regime of natural fertility, where parity does not affect a woman's subsequent behavior.

In a manual written with Michel Fleury (Fleury and Henry 1956), he laid out – to the minutest details – the rules for the processing of parish data. These rules have been followed faithfully by demographic historians, not only in France but also in other European countries such as England, where they guided the work of the Cambridge Group for the History of Population and Social Structure, and in Canada. Henry would publish another textbook on historical demography (Henry, 1967). Moreover, applying the vast experience accumulated in his early parish studies, he initiated a study of rural France, using a representative sample of French parishes during the eighteenth century. He analyzed this material by aggregative methods, and for a smaller sample of parishes used nominal information to reconstitute families. The project provided the first national series of estimates of fertility, mortality, and nuptiality for a Western European country in the eighteenth century. This body of work makes Louis Henry the uncontested father of historical demography as it is practiced today.

Mining the past for data on populations that did not consciously limit their family size was initially only a tool towards measuring the physiological components of human reproduction. Henry identified the factors to be considered as fecondability, the probability that a conception would result in a live birth; the delay in the resumption of ovulation after a delivery or nonsusceptible period, and total or partial sterility. He provided estimates of the value of these parameters on the basis of his own historical studies of population, but also of various accurate measurements made on other selected populations. His work was picked up by English and American demographers and biometricians working on fertility models, and among them by Mendel Sheps and Jane Menken who edited a collection of translations from Henry's most important articles (Henry, 1972). The seminal importance of Henry's work was acknowledged by the Population Association of America

[†] Deceased.

when it made him the first recipient of the Irene B. Taeuber Award for Excellence in Demographic Research in 1977. Just before his death in 1991, the International Union for the Scientific Study of Population had named him its first Laureate.

The concept of natural fertility is often considered as one of Henry's most significant contributions to population studies. He did not invent the term, but he defined it rigorously and provided means to identify natural fertility regimes. It refers specifically to the behavior of married couples, and is therefore not affected by variations in the proportions married and the age at marriage. Natural fertility is compatible with behavior that may affect the levels of natural fertility (frequency of intercourse, length of breast feeding) or even with attempts to space birth that are not depending on parity. Although the notion remains controversial, it has been used widely in the study of the fertility transition, both in the West and in today's developing countries.

Hermeneutics

Abstract

The methodology of interpretation has traditionally been called 'hermeneutics.' This article begins with elucidation of the central concept of hermeneutics and distinguishes it from other usages of the term. The subsequent sections clarify the relevant notion of methodology and the leading concepts of hermeneutics, *understanding* and *interpretation*. A glance at the history of hermeneutics focuses on turning points in the historical development of methodologies of interpretation. The concluding section seeks to bring out the main issues in the methods controversies of the nineteenth and twentieth centuries and to suggest strategies to resolve these controversies.

Hermeneutics: Concepts and Tasks

Hermeneutics is a discipline that sets itself upon the task of specifying and justifying *a methodology of interpretation*, originally of texts, but by extension of many other interpretanda. It has also been called the science or art of interpretation.

The Latin half-neologism 'hermeneutica' was introduced into scientific terminology shortly before 1630 by the German philosopher and theologian Johann Conrad Dannhauer (1603–66) as an equivalent of the old Greek term 'hermé-neutike [techné]' (=hermeneutic [art]) that in turn derives from the verb 'hermeneúein,' meaning originally 'to express' or 'to translate,' but since the days of Plato also 'to interpret' (cf Jaeger, 1974). Dannhauer's *Idea boni interpretis et malitiosi calumniatoris* was the first textbook of the new discipline called 'hermeneutica generalis' (Dannhauer, 1630).

It has been a common practice to distinguish between (1) a *general* hermeneutics covering all interpreting disciplines and (2) several *domain- or discipline-specific* subspecies of hermeneutics including, particularly, *hermeneutica sacra*, that is, bible hermeneutics (cf von Reventlow, 1990–2001), and *hermeneutica iuris*, that is, legal hermeneutics (cf Schröder, 2001), and also archaeological (Robert, 1919), historical (Bernheim, 1908: Chapter 5), literary (cf Szondi, 1975; Weimar, 1975), art-historical (Bätschmann, 1984), and musical hermeneutics (Dahlhaus, 1975). While general hermeneutics has traditionally been conceived as a philosophical discipline, commonly as part of logic in a wide sense (including methodology and parts of what is nowadays called epistemology), the different kinds of special hermeneutics have usually been assigned to their respective disciplines (bible hermeneutics to theology, literary hermeneutics to literary studies, and so on), although some philosophers preferred to regard the domain-specific arts of interpretation as mere applications of general hermeneutics to a special object.

Since interpretation is a means to understanding, *general hermeneutics* has two leading concepts, understanding and interpretation, and should, accordingly, consist of two main parts: (1) a theory, or at least a conception, of understanding and (2) a methodology of interpretation. As long as the objects of understanding were restricted to texts, theories of understanding accordingly amounted to conceptions of textual meaning. When the scope is broadened to include other objects of understanding (e.g., persons, actions, and artifacts), more comprehensive theories of understanding are needed. A methodology of interpretation should contain (1) a conception of the aims of interpretation (cf Bühler, 2003; Tepe, 2007) and (2) a system of principles of interpretation, including rules for the critical testing of interpretational hypotheses (cf Bühler, 2003; Scholz, 1999, 2014).

In more recent times, the technical term 'philosophical hermeneutics' has been applied to a philosophical program associated with the names of Martin Heidegger (1889–1976) and Hans-Georg Gadamer (1900–2002) that differs considerably from traditional hermeneutics. Early Heidegger had in mind a phenomenology or existential analytic of *Dasein* (i.e., human existence) that should replace traditional ontology (Heidegger, 1962). Gadamer's project was the more modest one of a phenomenology of hermeneutic experience, with special emphasis on the acquisition of the classical tradition (Gadamer, 1960). While Heidegger boldly appropriated the venerable term 'hermeneutics' for the peculiar brand of proto-anthropology he outlined in *Sein und Zeit*, Gadamer, much more cautiously, tried to use some of Heidegger's ideas to the benefit of philosophical esthetics and the humane studies. In his later years, Gadamer preferred to call his overall project 'hermeneutic philosophy' to avoid confusion with classical hermeneutics. Whatever merits Heidegger's and Gadamer's contributions might have, they should not be praised for 'deepening' the traditional project of hermeneutics; rather, they should be taken to have addressed, by and large, different questions and pursued different goals. Most importantly, they showed no interest in epistemological and methodological questions concerning interpretation. (The very title of Gadamer's *opus magnum* – *Truth and Method* – is meant to hint at its central thesis that truth in art and in the humanities lies outside the control of scientific methods.)

Today, 'hermeneutics' is frequently used to allude to a loose family of antinaturalist approaches in humanities and social sciences. Besides 'hermeneutics,' many social scientists employ terms like 'interpretive social science,' 'interpretive anthropology,' and 'interpretive theory of culture' (Geertz, 1973) or refer, more generally, to an 'interpretive turn' or 'interpretivism' in social sciences (Rabinow and Sullivan, 1987). In American sociology, it has been common practice to use *Verstehen* (Abel, 1929, 1948) or derivative terms such as 'the doctrine of

Verstehen' (Martin, 1969, 1970: Chapter 8) to refer to a technical use of 'understanding' in the work of Wilhelm Dilthey (1833–1911), namely 'empathic understanding,' and especially to the conception of a 'verstehende Soziologie'; that is, interpretive sociology, that was inaugurated by Max Weber (1864–1920) and soon became influential in German and American sociology (cf the critical discussions in Truzzi, 1974 and Martin, 2000). In addition, well-known German scholars following Dilthey – inter alia Eduard Spranger (1882–1963) and Karl Jaspers (1883–1969) – called for a 'verstehende' (interpretive) or 'geisteswissenschaftliche' (humanistic) psychology to counterbalance the dominant research program of an explanatory psychology (cf the critical discussion in Störring, 1928).

The present article focuses on general hermeneutics in the traditional methodological sense and its impact on the humanities and the social sciences. Other so-called 'hermeneutical' or 'interpretive' approaches are taken into account only insofar as they promise to be relevant for the methodological issues.

Methods and Methodology

A *methodology* for a field of activities is a specification of the basic methods that are recommended to be followed in this field. A *method* in turn is a teachable step-by-step procedure that is suited to solve specific practical or theoretical problems. It is useful to distinguish between *special scientific methods* that are specific for particular sciences or a well-defined subgroup of sciences and *general scientific methods* that are applied in all empirical sciences (cf Kraft, 1925). To be sure, a reasonable method need not and in most cases will not provide an algorithm for solving problems in a specified domain; but, insofar as hermeneutics claims scientific status, it should employ accepted scientific methods.

Hermeneutics may be conceived as either a descriptive or a normative discipline. In a *descriptive* vein, it aims at a rational reconstruction of an already existing practice of interpretation that presumably is less than perfect. In a *normative* vein, the goal is to direct, control, and, hopefully, to optimize this imperfect practice. Both projects, the descriptive and the normative, do seem not only legitimate, but also worthwhile.

Understanding and Interpretation

As noted above, the two leading concepts of hermeneutics are interpretation and understanding. Interpretation is a rational activity directed toward the cognitive aim of correct or adequate understanding. (The product of this activity is also called 'an interpretation.')

'To interpret' and 'to understand' are transitive verbs; understanding, like interpretation, has an object. One understands something (x), or one fails to understand it. Sometimes we understand something without effort, simply because we have acquired the requisite ability, and nothing more is needed. Thus, for example, we understand the linguistic utterance 'Piss off!,' since we have learned the English language. But, often, understanding requires work; this is revealed in phrases like 'trying to understand' or 'struggling to understand' (Vendler, 1994). When we cannot understand something immediately, we may nevertheless make an effort to understand it. Interpretation of x is necessary whenever there are special difficulties in understanding x. Such difficulties may be of different sorts (cf Rosenberg, 1981): (1) Thus, difficulty of understanding x is sometimes due to the intrinsic complexity of x; what is needed in such cases is some sort of analysis or decomposition (Ziff, 1972; Moravcsik, 1979). (2) In other cases, x may be difficult to understand because it does not fit coherently in a larger context; here what is required is rather some kind of synthesis or of embedding x in a network of connections. (3) In still other cases, difficulty of understanding x may be a question of the indistinctness of x, so that a careful tracing of boundaries or a better articulation might help.

What kinds of items are possible objects of understanding and interpretation? Traditional hermeneutics concentrated on the interpretation of texts plus, occasionally, things that were supposed to be sufficiently text-like. Reading in a book had been the great paradigm of understanding and interpretation the two most eminent cases being: reading in the book of nature (*liber naturae*) and reading in the Holy Bible, the *liber supernaturalis* (cf Danneberg, 2003).

For centuries, interpreters aimed at understanding and teaching others to understand canonical texts, inter alia Homer's and Hesiod's epics and myths, the works of Plato and Aristotle, Virgil's *Aeneid*, Ovid's *Metamorphoses*, the Holy Bible and the Corpus Iuris. Some of them maintained that in order to understand texts, we should also try to understand their authors. From a more systematic point of view, the objects of understanding may be divided into the following classes (cf Föllesdal, 1981; Scholz, 2010): (1) *persons* and collectives of persons; (2) intentional *attitudes* of persons, especially their cognitive and conative attitudes; (3) individual and collective *actions*; (4) certain *products of actions*; (5) *situations*; and (6) *rules* and rule-constituted social entities, for example, institutions (Wittgenstein, 1958; Nemirow, 1995). With regard to subclass (4), that is, products of actions, it should be emphasized that it encompasses a great variety of items: signs, signals, symbols, words, sentences, texts, arguments, proofs, paintings, maps, diagrams, sculptures, works of architecture, instruments, machines, and other artifacts. The understanding of languages and, more generally, symbol systems (cf Goodman, 1968) has sometimes been treated as a special case of (4) and sometimes as a special case of (6).

Common usage and common sense would certainly add one more item to the list, namely: (7) *natural phenomena*. At any rate, scientists and other curious people have always talked about understanding the universe and its many properties, structures, and mechanisms (cf Cooper, 1994); thus, we want to understand, for example, what osmosis is and how it works, or why there are black holes, and what their typical causes and effects are. But, although many representatives of classical semiotics and hermeneutics (e.g., Meier, 1757) had included natural signs in their domain, in more recent times, class (7) has been contested as a proper object of a theory of understanding (see below).

In addition to the direct object constructions, we use other grammatical structures, for example, 'understanding that,' and, more importantly, indirect question constructions such as 'understanding why' or 'understanding how' (cf Bromberger,

1962, 1992; von Kutschera, 1981: Chapter 2; Vendler, 1984, 1994). Attempts to understand *x*, say an action, may still aim at answering various different questions about *x*, for example, what was done, why it was done, and for what purpose. Thus, attending to the indirect questions that may follow the verb 'to understand' provides us with a more fine-grained classification of types of understanding (e.g., 'understanding what was done' and 'understanding why *x* was done') than the focus on the direct object constructions (e.g., 'understanding action *x*').

Is there something that all objects of understanding have in common? A plausible although still rather vague suggestion is that they all have *structure* (cf Ziff, 1972; Moravcsik, 1979). A bit more precisely, understanding in all cases involves cognition of internal or external relations and interconnections (cf Martin, 1970; Franklin, 1995), especially causal nexuses and nexuses of reference and meaning (cf Mantzavinos, 2005), and also logical relations (as in understanding a proof or an argument), means–end relations (as in understanding actions and artifacts), nomological relations (as in understanding events) and convention-based relations (as in understanding institutions) etc. (Scholz, 2014).

A Glance at the History of Hermeneutics

Hermeneutics has a long and rich history (cf Scholz, 1999: Pt. I; Schönert and Vollhardt, 2005; Detel, 2011; Böhl et al., 2013). The historiography of hermeneutics has been deeply influenced by the insufficient historical studies of Wilhelm Dilthey (1833–1911) and Joachim Wach (1898–1955), and as a result of that has been highly selective and often biased (cf Dilthey, 1900, 1966; Wach, 1926–33). Especially, the elaborate systems of general hermeneutics that emerged long before Friedrich Daniel Ernst Schleiermacher (1768–1834), Dilthey's great hero, have been unduly neglected. Another source of error is the temptation to invent whiggish narratives of a history that leads in an inexorable march of progress from alleged primitive beginnings to the alleged masters of present-day hermeneutics.

Prehistory

While the history of hermeneutics, strictly speaking, begins in the early modern period, its prehistory dates back to Greek antiquity where there is already a highly developed practice and experience of interpreting, inter alia, oracles, dreams, and other signs, myths and epics, philosophical and poetical works, the deeds and works of famous human beings as well as laws, contracts, and testaments. First attempts at explicitly formulating and systematizing rules of interpretation can be found in ancient grammar and rhetoric (cf Pfeiffer, 1968; Eden, 1997), in Galenus and the Hellenistic commentators of Plato and Aristotle (Jaeger, 1974) as well as in Rabbinic and Early Christian exegesis (von Reventlow, 1990–2001).

The most salient and important tendency of ancient exegesis was *allegoresis*, a method of nonliteral interpretation of authoritative texts that contained statements that prima facie seemed either (1) morally or theologically inappropriate, or (2) false. In order to 'rescue' or defend these texts, interpreters were urged to find a deeper sense (*hypónoia*; 'underlying meaning') or allegorical meaning (*allegoría*, from *alla agoreuein*, 'saying something different') and to ascribe it to the offensive passages such that the wording can be maintained, but the alleged imperfections of the text disappear. Allegoresis was practiced widely from the sixth century BC to the Stoic and the Neoplatonistic schools and beyond. It was, however, rejected by others, most notably by Plato, by the Epicureans (with the exception of Lucretius), and by the Alexandrian scholars (Eratosthenes, Aristarchus).

In late antiquity and the Middle Ages, the ancient techniques of allegorical interpretation developed into complex systems of threefold or fourfold written meaning that were applied mainly to the Bible, and also to natural things (cf von Dobschütz, 1921; de Lubac, 1959–64; Ohly, 1977; Brinkmann, 1980).

In the tradition of the eminent commentators, the preliminary questions of interpretation were summarized in the so-called *accessus ad auctores* that preceded commentaries, translations, and editions of Aristotle, Porphyry, Virgil, and other classical authors. Three major traditions, literary, rhetorical, and philosophical, lead to overlapping, but somewhat different typologies of the hermeneutical tasks. The literary tradition (Servius) emphasized questions about the biography of the poet (*vita poetae*), the title of the work (*titulus operis*), the quality of the poem (*qualitas carminis*), the author's intention (*intentio scribentis*), and the division of the text (*numerus librorum*, *ordo librorum*). In the rhetorical tradition (from Cicero to Erasmus), the tasks were derived from an analysis of the *circumstantiae orationis*, in modern terminology from features of the context of a speech or written text (especially place, time, and author) which were usually indicated by the corresponding questions (*quis*, *quid*, *cur*, *quomodo*, *quando*, *ubi*, *quibus facultatibus*). In the philosophical tradition (Alexander Aphrodisias, Ammonius, Simplicius et al.), the commentators also asked questions about the title and the author of the work; a good interpreter, however, should not only concentrate on the purpose or intention of the work (*skopós*; *intentio operis*), its theme, structure, and internal connections, but also take into consideration its utility and ask himself to which part of philosophy it belongs. The philosophical *accessus ad auctores* could be systematized in the Middle ages in terms of Aristotle's doctrine of four causes identifying the author as efficient cause, the themes, and sources of the text as material cause, the proceeding of the author and the form of the text as the formal cause, and the purpose of the work as final cause.

Early History

In the early modern period, the 'rationes' and 'media interpretationis' known from antiquity were assembled and integrated into a new conception of education and methodology (Piccart, 1605a,b; cf Jaeger, 1974; Kessler, 2002). Several Aristotelian and eclectic philosophers, among them Clemens Timpler (1567–1624), Bartholomaeus Keckermann (1571–1609), and Michael Piccart (1574–1620), called for a new discipline that would teach us to be good interpreters and to avoid intentional and unintentional misinterpretations (cf Jaeger, 1974; Sdzuj, 1997). Such a discipline was badly needed for several reasons: (1) Without it, a rich potential source of knowledge, namely all oral and written testimony, was in danger of being spoiled and ruined. (2) It promised to provide a neutral ground from which many theological and confessional controversies could be settled. This new

self-consciousness culminated in the *Idea boni interpretis et malitiosi calumniatoris* (1630) by Johann Conrad Dannhauer (Jaeger, 1974; Sdzuj, 1997). Shortly before he presented the first systematic textbook on general hermeneutics, he had introduced the Latin half-neologism *hermeneutica* as the title of a new *modus sciendi* intended to supplement the Aristotelian *Organon*. It is general in that it is common to all sciences ('omniis scientiis communis') and useful for scholars of all faculties ('omnium facultatum studiosis perquam utilis').

After Dannhauer had established the systematic *locus* of hermeneutics within logic (Dannhauer, 1630, 1634), eminent philosophers such as Johann Clauberg (1622–65), Christian Thomasius (1655–1728), and Christian Wolff (1679–1754) devoted integral parts of their logical writings to general hermeneutics (cf Bühler, 1994; Schönert and Vollhardt, 2005). Thus, from Dannhauer to Bernard Bolzano (1781–1848), it became a regular component of logic textbooks or logic-based treatises, either as an integral part of Aristotelian logic or as a separate practical logic (Scholz, 1999).

The idea of a general hermeneutics evoked the widest interest in the seventeenth and eighteenth centuries, and there emerged a number of alternative outlines in the different philosophical schools (Alexander, 1993; Bühler, 1994; Sdzuj, 1997). I can mention only two conceptions which seem to me both of historical and of intrinsic interest: (1) On the one hand, there is the Rationalist project of a systematic general hermeneutics as envisaged in the Cartesian and Wolffian schools with their methodological ideal of an axiomatic–deductive system. Thus Clauberg, in his sophisticated hermeneutics, made distinctions between the rules of interpretation with regard to their generality, from the most general principles (Clauberg, 1654: §§. 86–89) to the special rules of interpretation (Clauberg, 1654: §§ 90–104). Among the most general principles are what may be called principles of benevolent interpretation (cf Künne, 1990), for example, 'in dubiis benigniora eligere,' that is, in cases of doubt to choose the more benign interpretations, or 'dubium in meliorem partem esse accipiendum,' that is, the doubtful is to be understood for the better (Clauberg, 1654). Or to take an extreme example, Wolffians Alexander Gottlieb Baumgarten (1717–62) and Georg Friedrich Meier (1718–77) emphasized the principle of hermeneutic equity (*aequitas hermeneutica*) – according to which the interpreter should interpret any sign in such a way that his interpretation tallies with the presumption of the perfection of the sign and its author (until the opposite has been proven) – as *the* first principle of general hermeneutics (Meier, 1757; cf Scholz, 1999). (2) On the other hand, there is the empiricist idea of a general hermeneutics as a theory of hermeneutic probability that was elaborated by the school of Christian Thomasius (1655–1728) and Andreas Rüdiger (1673–1731). Thus, Christian August Crusius (1715–75), in his excellent hermeneutics, enumerated the most general presumptions of hermeneutic probability, among them, defeasible presumptions of logical consistency and means–ends rationality (Crusius, 1747; cf Scholz, 1999).

It should be clear by now that when the theologian Friedrich Daniel Ernst Schleiermacher (1768–1834) propagated, with great emphasis, a 'general hermeneutics' at the beginning of the nineteenth century, he was (albeit in his own distinctive way) reinventing the wheel. While his conception of general hermeneutics may be interesting in its own right, his claim that such a discipline did not already exist was simply false. Moreover, most of the rules he recommended were taken over from contemporary textbooks on bible hermeneutics. Any text or speech is to be understood, on the one hand, as part of a language and, on the other hand, as part of an individual life (Schleiermacher, 1977). Schleiermacher's conception of psychological interpretation and his emphasis on the individuality and originality of the author had a great influence on August Boeckh (1785–1867), Wilhelm Dilthey (1833–1911), and other modern theoreticians of hermeneutics.

Dilthey took an interest in the history of hermeneutics for two reasons: in the first place, because he was working on a comprehensive biography of Schleiermacher (cf Dilthey, 1966) and, secondly, because he thought hermeneutics developed his own project: a laying of the foundations of the new *Geisteswissenschaften* (history, national economy, jurisprudence, political science, religious studies, literary studies, art history, musicology, and psychology (!)) which he tried to demarcate strictly from the natural sciences (Dilthey, 1927). The common object of these human sciences is mankind and its history, the 'human–social–historical reality' or, in Hegelian terms, the world of objective spirit. The objects of the humanities are 'constituted' in a way that differs fundamentally from the way the objects of the natural sciences are 'constituted.' To reconstruct the constitution of the historical world is the central task of a 'logic' of the *Geisteswissenschaften*. According to Dilthey, the leading concepts of the human sciences are life or lived experience ('Erlebnis'), expression, and understanding. While we are only able to explain the connections of the physical world with the help of abstract concepts and theoretical extrapolations, our access to the mental and spiritual world is immediate: we are able to understand manifestations of life because we know the connection between the outward expression and something inner that is thereby expressed from our own case. In the elementary forms of understanding, we infer (by some kind of analogical reasoning) from a single manifestation of life that it is the expression of a certain inner content; in the higher forms of understanding, we try to reconstruct the totality of an individual life, for example, the life of Martin Luther, via a special form of induction that is, unfortunately, not analyzed in detail by Dilthey. It is in this context that he underlined the importance of reproduction ('Nachbildung') and re-living ('Nacherleben') for understanding other minds and their works. While the higher forms of understanding are initially based on the personal genius of the interpreter, for the purposes of historical sciences they have to be developed into a technique, the art of interpretation. According to Dilthey, the science of this art is hermeneutics (Dilthey, 1927).

Recent Developments

The Methods Controversies

One consequence of the emergence of the 'Geisteswissenschaften' (moral sciences; humanities) or 'Kulturwissenschaften' (cultural studies) was a long series of methods controversies ('Methodenstreite') that continue till today. Time and again, self-styled antipositivists and antinaturalists reacted to so-called positivists

and naturalists. (Since 'positivism' and 'naturalism' are mainly used in a pejorative sense, I prefer the more neutral terms 'Methodological Monism' and 'Methodological Dualism' to designate the main issue between the two camps: whether there is a methodological unity or a strict methodological separation.)

In the early stages of the controversy, Auguste Comte (1798–1857), John Stuart Mill (1806–73), and the historian Henry Thomas Buckle (1821–62) counted as the arch-positivists. In Germany, there was, in addition, the Leipzig Circle that included the experimental psychologist Wilhelm Wundt (1832–1920) and the historian Karl Gotthard Lamprecht (1856–1915). Comte, Mill, and their followers pleaded for applying the general 'logic' of scientific research to the humanities and social sciences. Mill expressed the hope that the desideratum of a 'Logic of the Moral Sciences' could be met by generalizing and adjusting the methodology that was developed for the natural sciences (Mill, 1843: Book VI, Chapter I, p. 1). In other words, the 'positivists' pleaded for the methodological unity of the sciences.

Their opponents insisted on a special methodological status of the *Geisteswissenschaften*, and in particular on a high degree of methodological autonomy of, say, history. Despite this fundamental consensus, they offered rather different suggestions for demarcating the two groups of sciences (cf Becher, 1921). Johann Gustav Droysen (1808–84) and Wilhelm Dilthey (1833–1911) famously opposed the method of 'Erklären' (explanation) as against the method of 'Verstehen' (understanding) (Droysen, 1977; Dilthey, 1924). The neo-Kantian philosophers Wilhelm Windelband (1848–1915) and Heinrich Rickert (1863–1936) focused on the respective aims of each group of sciences and especially on the methods of concept formation and judgment; according to them, the logic of history and, more generally, the logic of the *Kulturwissenschaften* is characterized by an idiographic interest in singular judgments about the past (Windelband, 1894) or in an individualizing form of concept formation (Rickert, 1929). In addition, they underlined that the objects of cultural studies are essentially related to shared cultural values ('wertbezogen').

While Dilthey and Rickert in their most exaggerated statements pleaded for a strict separation of the *Geistes-* or *Kulturwissenschaften* from the natural sciences, some contemporaries argued for more subtly differentiated positions. Thus, Max Weber (1864–1920) emphasized, on the one hand, that the sociologist must first try to understand human action in terms of the categories of the actors, their goals, and beliefs. On the other hand, he stressed that understanding of this kind has to be controlled by the usual methods of causal attribution (Weber, 1922). Thus, he avoided claiming an opposition between understanding and explanation. On the contrary, his 'verstehende Soziologie' (interpretive sociology) leads from interpretive understanding to a causal analysis of the actual processes (Ringer, 1997). His causalist methodology makes it possible to explain the conduct of actors that are quite unlike us. Against an overestimation of Diltheyan understanding qua congenial reliving, Weber, echoing Georg Simmel (1858–1918), reminded us that one need not be Caesar to understand Caesar (Weber, 1922; cf Simmel, 1905). Nevertheless, since Weber limits the subject matter of sociology to subjectively meaningful action, his intermediate position in the methods controversies is still too restrictive for the whole spectrum of social scientific understanding. Social scientists should try to explain behavior, for example, traditional behavior, that may no longer be subjectively meaningful; and they should be allowed to draw on regularities discovered by scientists from other disciplines in order to explain individual and collective behavior (Martin, 2000).

To the already mentioned alleged dichotomies (explanation versus understanding; nomothetic versus idiographic sciences), more recent methods that dualists have added: construing human actions as mere events from outside versus reenacting the thoughts of the agent in the historian's mind (Collingwood, 1946); covering law explanations versus rationalizing explanations (Dray, 1957), causes versus reasons (various ordinary language philosophers); causal explanations versus teleological explanations (von Wright, 1971); and so on.

Against Separation

One strategy to avoid the separation of disciplines implied by Methodological Dualism is to question the alleged dichotomies and their theoretical presuppositions. Thus, it has been argued that understanding is not a method in itself that can be contrasted with other methods, but the end at which all methods aim (Lundberg, 1939), or that the reasons for acting can at the same time be the causes of the action (Davidson, 1963). In addition, it has been argued that special mental operations aiming at understanding, for example, operations of reliving, reenacting, or empathic understanding, may be useful heuristic techniques, but cannot replace reliable methods for validating hypotheses (Hempel, 1942, 1965; Abel, 1948; Rudner, 1966). The most important objection to the idea that human action has to be understood 'from inside' or 'from the perspective of the agent' is that it would unduly restrict historical and social scientific understanding (Martin, 2000).

Another strategy to defend a fundamental methodological unity of the sciences is to focus on the most general scientific methods (cf Kraft, 1925), especially the methods for the critical testing and validating of hypotheses. At least since the nineteenth century most philosophers of science have favored some version of the Hypothetico-Deductive Method: Begin by forming hypotheses (including hypotheses about unobservable entities, processes, and forces), then deduce consequences about observable phenomena from these hypotheses, and finally examine whether these consequences fit in with the experiential data. In view of the generality and wide applicability of this method, it is not surprising that it has been suggested as the method of hermeneutics (cf Hirsch, 1967; Göttner, 1973; Föllesdal, 1979; Mantzavinos, 2005). And, it can hardly be denied that many interpreters have made use of this general kind of reasoning in their interpretive efforts. In my view, the Method of Inference to the Best Explanation is even more widely applicable: Ask yourself what would explain the available evidence and take the ability of a hypothesis to explain the relevant data as an indicator that the hypothesis is probably correct (cf Lipton, 2004). Applications of this general method are ubiquitous in all forms of inquiry. Moreover, it promises to be free from the serious logical and epistemological

problems that emerge when we try to make the Hypothetico-Deductive Method precise (Scholz, 2014).

A third strategy to overcome the method's controversies is to opt for an eclectic methodological pluralism that encourages all methodologies and theoretical approaches that seem to be relevant to the questions being asked and the aims pursued (cf Little, 1991; Martin, 2000). This strategy accepts the diversity of methods without separating the disciplines by an unbridgeable gulf.

Abstract

The term 'hermeneutics' refers to the science, art, or technique of interpretation, of written texts and, by extension, of human actions and other social phenomena. In this extended sense, it has come to denote a variety of approaches in the social and behavioral sciences ('*verstehende*' sociology, symbolic interactionism, social phenomenology, social constructionism, ethnomethodology). Hermeneutic or phenomenological approaches now coexist and are even combined with more structural conceptions of social science or ones modeled more closely on the natural sciences. Hermeneutics in this broader sense continues to exist as a major research tradition in the humanities, as well as a minority one in the social and behavioral sciences.

The term 'hermeneutics' refers to the science, art, or technique of interpretation, paradigmatically of written texts but by extension of human actions and other social phenomena. In this extended sense, it has come to denote a variety of approaches in the social and behavioral sciences. The word refers to the Greek messenger God Hermes, and reflection on the problems of interpretation and criteria for the truth, validity, or adequacy of interpretations, goes back to ancient Greek thought in the European tradition and a similar historical distance in the other world civilizations. We can consider this as the prehistory of hermeneutics, revived in the philological criticism of classical texts in the Renaissance, the interpretation of Roman law, the interpretation of the Bible in (especially Protestant) Christianity, and the philosophical analysis of texts.

The systematization of hermeneutics occurred largely in German-speaking Europe in the course of the nineteenth century, although two earlier thinkers deserve particular mention. Johann Martin Chladenius (1710–59) published in 1742 a general account of interpretation, which brought together traditional Aristotelian rhetoric and more recent Enlightenment themes, developing in particular the notion of point of view or perspective (*Sehe-Punkt*), crucial to later philosophy of history and social theory through to Karl Mannheim (1893–1947) and beyond (Mueller-Vollmer, 1986). Second, Giambattista Vico (1688–1744) formulated the basic principle that our knowledge of what we ourselves have made (individually or collectively) is different from what we have not made. The world of human society and culture is in some sense 'our' product.

This distinction, crucial to later hermeneutics and 'hermeneutic' social science, between what we know from the inside and what we know because we have learned about it is taken up in a rather more speculative form in Hegel's differentiation between reason (*Vernunft*) and the understanding (*Verstand*), although the maker here is the world spirit coming to recognize its own productions (including, ultimately, the world itself) and its learning processes as rational, in contrast to the essentially contingent states and relations found in nature and described by the mathematical and natural sciences. Something more like Vico's idea returns again in the second half of the nineteenth century, when Hegel's concept of objective mind is extracted from its surrounding developmental 'grand narrative' and treated more as a descriptive category.

It was Friedrich Schleiermacher (1768–1834), following Friedrich Schlegel, who consolidated hermeneutics in a systematic form, establishing the term understanding (*Verstehen*), which had been used by Chladenius and which has survived as standard usage in English-language social science discourse, and making it central to interpretation – understood as a more systematic activity. Interpretation here involves both the linguistic understanding of meaning and a psychological understanding of the author's intention. Schleiermacher introduced the distinction between technical and more developed or speculative forms of interpretation and formulated the much-discussed principle that it should be possible to understand an author better than he understood himself. Schleiermacher's contribution was made the central and culminating point of the account of 'the rise of hermeneutics' given by Wilhelm Dilthey (1833–1911); with Dilthey, hermeneutics becomes central to the self-definition of what he called the human sciences or *Geisteswissenschaften*. In these sciences, as Dilthey put it, the mental activity of humans and of some other animals, and its products, can be understood.

Dilthey and his contemporary, the philosopher of history J. Gustav Droysen (1808–84), developed what we would now call a research program for history and the other human sciences based on the distinctiveness of human psychic expressions and the understanding of those expressions. In a move that was to become a definitional feature of later interpretive social science, Dilthey, like Schleiermacher, emphasized the continuity between everyday understanding and more formal processes of interpretation. His distinction between the natural and human sciences was developed in large part in opposition to Comtean positivism, which had become influential, even in the German-speaking countries, by the middle of the nineteenth century. In a parallel, but more methodological formulation, two other neo-Kantian thinkers, Wilhelm Windelband (1848–1915) and Heinrich Rickert (1863–1936), argued that the study of culture is essentially concerned with individual processes and relating them to shared human values, whereas the natural sciences are concerned with general laws about objects that are essentially remote from questions of value. We are interested, for example, in the French Revolution, not just as a member of a class of revolutions exhibiting certain common features (this would

be, for Rickert, a natural-scientific mode of approaching it), but as a unique event embodying, and perhaps also violating, certain crucial human values.

This opposition between positivism and methodological dualism, and more particularly between causal explanation, analyzed in terms of universal regularities, and 'understanding' comes to structure the emergent human or social sciences, as the term 'culture' increasingly gives way to 'society' or 'sociation' (*Vergesellschaftung*). There is a fairly strong line of influence from Rickert to Max Weber, both directly and also through his friend Georg Simmel, who discusses our knowledge of the social world in terms that foreshadow social constructionist theory (*see* Constructivism/Constructionism: Methodology).

Max Weber's personal development from economic and legal historian to sociologist continues the encounter between hermeneutics and the social sciences, which had been a dominant feature of the late nineteenth century, and he also develops a middle position on the issue of methodological dualism, as he had earlier on the related opposition in economic theory (the *Methodenstreit*) between the pursuit of a systematic law and a more interdisciplinary and historical approach. For Weber, as he put it in an early essay, "the course of human action and every sort of human expressions are susceptible to meaningful interpretation; in the case of other objects, an analogous interpretation would only be possible in the sphere of metaphysics" (Weber, 2012: p. 10). He therefore later defines sociology, in the first sentence of his major work *Economy and Society*, as a science that aims at an interpretative understanding of action in order thereby to understand its course and effects. Whether by this Weber means that explanatory understanding is itself a form of causal explanation, or merely complementary to it, the crucial point for him is that explanations of social phenomena must be both 'causally adequate' and 'meaningfully adequate.'

For Weber, then, our access to knowledge of the social world is importantly different from our knowledge of nature. However, it is not, in his view, any less objective. He heroically attempts to hold together Rickert's principle that our perspectives on cultural phenomena, and our knowledge of them, are shaped by values (based for Weber on ultimately ungroundable existential choices), with the idea that the social sciences can attain a bedrock of solid and 'value-free' knowledge, which would have to be accepted, as he sometimes curiously puts it, 'even by a Chinese (Weber, 2012: p. 105)'. Weber insists that it is the intentions and purposes (subjective meanings) of human actors that define their actions and therefore have to be understood by the historian or sociologist, but he moves rapidly to the construction of a system of ideal types of action orientation less limited than that found in economic theory but still substantially dependent on it.

Weber's synthesis was pulled apart from both sides in the decades following his early death in 1920. At one pole, there was now a more stridently naturalistic and indeed reductionist variant of positivism: the logical empiricism of the Vienna Circle, in whose 'unified science' the statements of all sciences should be ultimately reducible to material–object language or to statements in physics; *Verstehen* was of no more importance, in Otto Neurath's vigorous formulation, than a good cup of coffee, which sustains the social scientist (Neurath, 1973: p. 357).

From the other direction, Alfred Schutz initiated the tradition of social phenomenology, and what is often loosely called 'hermeneutics' in the context of the social sciences, with a book published in Vienna in 1932 with the title *The Meaningful Constitution of the Social World*. Schutz felt that the problem with Weber's ideal types was not that they were insufficiently scientific, but precisely the opposite: Weber was too quick to impose them on the phenomena he described, paying insufficient attention to their grounding in acts of typification performed by ordinary members of society. For Schutz, the social scientist is merely constructing second-order typifications based on those already carried out in the lifeworld. This theme was taken up by the phenomenologist Aron Gurwitsch in the United States, where Schutz had also settled, and by Peter Berger and Thomas Luckmann (1967), who finally put the term 'social construction' on the map, offering in the guise of a sociology of knowledge a paradigm more directly adapted to use in social research. By the time Schutz's first book was republished, in Austria in 1960 and in the United States in 1967, the way was prepared by his own later work and, in the English-speaking world, by Berger and Luckmann (1967).

The middle decades of the twentieth century replay many of the debates, which had dominated the second half of the nineteenth century. Droysen's complaint, in a letter of 1852, about the rise of what he called 'crass positivism,' and his crusade against it in a course, which he taught from 1857 onward, is echoed by antinaturalist social science just over a hundred years later. Social phenomenology also of course had affinities with the well-established minority tradition in North American social science of symbolic interactionism; this also experienced a certain resurgence in the 1960s with, for example, the republication of the work of G.H. Mead and that of Herbert Blumer, and also the publication of various studies by Erving Goffman (Helle, 2005). But where the interactionists tended not to spend time on formal critiques of empiricism, Harold Garfinkel's ethnomethodology (Garfinkel, 1967) was more aggressive. A former student of the structural functionalist Talcott Parsons, Garfinkel was led by his study of the deliberations of a trial jury to emphasize, like Schutz, the importance of practical reasoning in everyday situations. He showed that our drive to interpret leads us to impute a meaning even to random processes in the social world, as in one of his later experiments in which an interviewer playing the role of a counselor replied to the clients' questions by a random 'yes' or 'no,' leading them into more and more contorted interpretative efforts. The production of meaning is at the same time the production of social order – Parsons' major concern. Unlike his former teacher, however, Garfinkel insisted that social actors are not simply bearers of their social roles ('cultural dopes'), but active subjects obliged to practice social analysis in order to function in everyday society.

Social phenomenology found a somewhat unexpected ally in a convergent move within analytic philosophy. Having been close to the Vienna Circle, Ludwig Wittgenstein came to abandon the simple conception of a picturing relation between propositions and the world, and was drawn into a more sensitive and holistic analysis of the practicalities of 'language games,' based on implicit rules and embedded in what he enigmatically called 'forms of life.' An important book by the Wittgensteinian philosopher Peter Winch (1958) drew the

consequences for social theory, using Max Weber, as Schutz had done, as one of the foils for his argument. For Winch, knowing a society meant learning the way it is conceptualized by its members. He thus revived the central principle of nineteenth century German historicism, according to which every age must be understood in its own terms. Winch directly identified himself with the German idealist tradition by insisting that social relations are 'like' logical relations between propositions (1958: p. 126) and encouraged an ethnographic fieldwork approach, which often includes language learning in the research process.

Analytic philosophy of language was also drawn on by the anthropologist Clifford Geertz (1973) in his very influential defense of what, following the English philosopher Gilbert Ryle (1949), he called 'thick description' (Luhrmann). For Ryle, a thick description is one, which can, for example, differentiate between the twitch of an eyelid and a wink, with all its complex contextual and cultural connotations. Geertz' classic account of cockfighting in Bali exemplifies this approach, moving from a sensitive description of the practice to a broader consideration of its cultural significance. This relatively informal research strategy, which has affinities with what Glaser and Strauss (1967) called 'grounded theory,' can be contrasted with more formal approaches such as functionalism and structuralism. It is sometimes framed in terms of the use of 'emic' (actors') as opposed to 'etic' (observers') categories, terms based on the linguistic distinction between phonemic and phonetic (Pike, 1966; article on cultural ecology). Geertz himself deprecated this usage, as well as that of 'verstehen': an 'actor-oriented' anthropological interpretation is usually too casually referred to as 'seeing things from the actor's point of view,' too bookishly as 'the *verstehen approach*,' or too technically as 'emic analysis…' (Geertz, 1973: p. 14).

Hermeneutic theory itself took a new turn with the 'philosophical hermeneutics' of Hans-Georg Gadamer (1900–2002), whose *Truth and Method*, published in 1960 and translated into English in 1975, insists, in opposition to historicist hermeneutics, on the practical dimension of interpretation, conceived in Heidegger's sense of an 'encounter' between the 'horizon' of the interpreter and that of the text itself. Gadamer's philosophical hermeneutics is thus set in opposition to the methodological emphasis of traditional hermeneutic theories and their concern with the accuracy of interpretation. Gadamer's aim is to describe the underlying process, an existential encounter between two perspectives or horizons of expectation, which makes interpretation possible in the first place. Understanding is not just a matter of immersing oneself imaginatively in the world of the historical actor or text, but a more reflective and practical process that operates with an awareness of the temporal and conceptual distance between text and interpreter and of the ways in which the text has been and continues to be reinterpreted and to exercise an influence over us. This effective history (*Wirkungsgeschichte*), which traditional historicist hermeneutics tends to see as an obstacle, is for Gadamer an essential element that links us to the text. Our prejudgments or prejudices are what make understanding possible.

Although Gadamer has often stressed that his philosophical hermeneutics, with its origin in Heidegger's hermeneutic ontology, is distinct from hermeneutics as a technique of interpretation, his approach clearly poses a challenge to more traditional conceptions of hermeneutics. These differences are brought out in particular in Gadamer's exchanges in the 1960s with Emilio Betti. The alternative conception of the human sciences or *Geisteswissenschaften* put forward in Gadamer's work also made it central to Jürgen Habermas' reformulation of the 'logic of the social sciences' (Habermas, 1988[1967]). Habermas welcomed Gadamer's critique of hermeneutic objectivism, which he saw as the equivalent of positivism in the philosophy of the natural sciences, and also his stress on the totalizing character of understanding. For Habermas, however, Gadamer's stress on the fundamental nature of language, as expressed in his claim that 'Being that can be understood is language,' amounted to a form of linguistic idealism. Together with Gadamer's stress on the importance of tradition and his rehabilitation of the category of prejudice, this suggested an ultimately conservative approach, which was unable to deal with the 'systematic distortion' of communicative processes by relations of power and domination. Habermas and Gadamer debated these issues in the late 1960s and early 1970s (Bleicher, 1980); more recent theorists have tended to stress the compatibility of hermeneutics and critical theory in a conception of critical hermeneutics (Thompson, 1981; Giddens, 1984b; Outhwaite, 1987; Kögler, 1996a, 1996b). Gadamer also engaged briefly with the French deconstructionist philosopher Jacques Derrida, whose conception of interpretation was more skeptical (Silverman and Ihde, 1985; Michelfelder and Palmer, 1989; Bernstein, 2008). Another major French philosopher, Paul Ricoeur (1913–2005), engaged more directly with hermeneutic issues in the social sciences, in his book on Freud (Ricoeur, 1970[1965]), in which he formulated his concept of a 'hermeneutics of suspicion,' in his response to the Habermas–Gadamer debate, and in a large number of other essays (Ricoeur, 1981a,b, 1991, 2010). He addressed in particular the question of analyzing action in textual terms (Ricoeur, 1973).

Habermas' version of 'critical theory' can be seen, along with critical realism and Anthony Giddens' structuration theory, as one of the three particularly influential attempts in the final third of the twentieth century to reconcile, as Max Weber had done at the beginning of the century, the rival claims of explanation and understanding in the social sciences. Habermas, along with his close collaborator Karl-Otto Apel, argued for a complementarity between an empirical–analytic approach oriented to the explanation, prediction, and control of objectified processes and a hermeneutic approach concerned with the extension of understanding; these combined in an emancipatory model of critical social science, instantiated by psychoanalysis and the Marxist critique of ideology, which aims at the removal of causal blocks on understanding. Much of this remains in Habermas's more recent theories of reconstructive science and communicative action.

Critical theory tends toward a dualism of natural and social science, but in an increasingly muted form. The assumption that opposition to positivism also entailed dualism or anti-naturalism was, however, also put in question in the late 1960s and early 1970s by the realist metatheory of science developed by Rom Harré and Roy Bhaskar (1975). Both Harré and Bhaskar, like Habermas, were substantially motivated by the desire to undermine positivistic theories and approaches in the

social sciences. Harré and Secord (1972) developed a philosophy for social psychology based on the work of the later Wittgenstein and the analytic philosophy of language practiced at Oxford by John L. Austin (1911–60). Ordinary language, they argued, is better suited to the description of the mental processes of social actors than apparently more scientific artificial terminology, and they drew attention to models of research practice of this kind in the work of Goffman, Garfinkel, and others.

Harré and Bhaskar were in any case interested in giving a more adequate account of science as a whole, in a world composed of relatively enduring structures and mechanisms. Some of these could be isolated in scientific experimentation, given the contingent existence of *homo sapiens* and *homo scientificus*. An important aspect of the realist program developed by Harré, Bhaskar, and others was a conception of explanation as involving not an essentially semantic reduction of causal statements to general laws but a reference to the causal *powers* of entities, structures, and mechanisms. Causal tendencies might or might not be outweighed by countervailing tendencies, and two causal tendencies may neutralize one another, as do the centrifugal force of the Earth's rotation and its gravitational attraction, with the convenient consequence that human beings and other animals are safely anchored to the Earth's surface.

This and other features of realism meant that the whole issue of naturalism could be rethought. Human beings could be seen as having causal powers and liabilities, just like other entities; it no longer mattered so much that their relations rarely sustained any universal generalizations of an interesting kind, but only sets of tendencies regular enough to be worth exploring. The fact that many of the entities accorded causal force in social scientific explanations were necessarily unobservable was not, as it was for empiricism, a problem of principle. And the understanding of meaning could, as Bhaskar (1979) put it, be seen as in some ways equivalent to measurement in the natural sciences. Finally, it seemed natural to include among the causes of human action the agents' reasons for acting – reasons that must be understood as far as possible.

The realist critique of traditional epistemology found an echo in social theory, notably in the work of Anthony Giddens, who had become similarly impatient with the residues of positivist social science as well as the more radical contentions of social constructionism. Giddens' conception of the 'duality of structure' was designed to replace the traditional dichotomies between theories of social structure and social change, the micro–macro divide, and between interpretive and more structural approaches. Approaches like these, which aim to mediate between pure hermeneutics and more naturalistic conceptions of social science, coexist, in the early twenty-first century, with more explicitly hermeneutic or phenomenological conceptions (see, e.g., Oevermann et al., 1987; Soeffner, 1989; Müller-Doohm and Jung, 1993; Luhrmann). Hermeneutics in a broader sense continues to exist as a major research tradition in the humanities, including the history of political thought (Richter, 2010) and intermediate fields such as 'critical discourse analysis' (Wodak and Meyer, 2009), as well as a minority one in the social sciences (Shapiro and Sica, 1984). More importantly perhaps, social scientists who would not sign up to an explicitly hermeneutic program have at least accepted the importance of hermeneutic issues.

Heterosexism and Homophobia

Abstract

Acceptance of homosexuality is increasing in Western cultures, but homophobic negative, fearful, or hateful attitudes and behavior toward gays, lesbians, and bisexuals are still pervasive in those same cultures. Social science studies emphasize that homophobia is deeply rooted in cultural beliefs about gender and supported by heterosexist assumptions that only heterosexual relationships are natural and normal. Homophobia is institutionalized through the actions of law enforcement, the judiciary, politicians, and religious leaders, as well as through public support for continued homophobic discrimination. Challenges to homophobic social practices are rising, but action to insure the rights of all sexual minorities remains essential.

Homophobiais a form of cultural prejudice that includes negative, fearful, or hateful attitudes and behavior toward gays, lesbians, and bisexuals. One reason why lesbians, gay men, and bisexuals are the object of so much cultural fear and loathing is that homosexual sex does not conform to the gendered or reproductive expectations of heterosexuality. The extent to which homophobia is a US institution is indicated in the decisions of law enforcement officials and judges who consider homosexuality sufficient grounds for justifying acts of prejudice, discrimination, and violence. This article will cover theories of homophobia and the normative expectations of heterosexuality, manifestations of homophobia, and a brief history of social movements related to homophobia.

Terminology

Before proceeding, it is important to note that there is debate about the use of the word 'homophobia' and the closely related word 'heterosexism'. Although homophobia is a commonly used term to indicate antilesbian and antigay prejudice, many social scientists (e.g., Adam, 1998; Plummer, 1992; Stein and Plummer, 1994) find it useful to distinguish analytically and conceptually between heterosexism, which they define as the societal prejudice located in the structures, institutions, and material conditions of society, and homophobia, which they define as the manifestation of the individual-level attitudes and behavior reflective of heterosexism. In Popular media, however, 'homophobia' commonly refers to both.

Heterosexism and homophobia are mutually constitutive: individuals feel that their antigay attitudes and behaviors are legitimate to the extent that these prejudices are entrenched in social institutions. Individuals are more likely to act out their prejudices when they consider them to be culturally legitimate and shared by others (Berrill, 1992). Expressions of antigay prejudice reinforce ideologies and practices of intolerance and hostility that suggest that homosexuality is something that should be despised and feared and should remain hidden.

Attitudes and Expressions of Homophobia

One common stereotype is that homosexuality is the same as gender-role nonconformity. It is frequently assumed that lesbians manifest characteristics defined as masculine and gay men exhibit behavior associated with feminine characteristics. For many people, this presumed gender nonconformity is reason enough to be suspicious and intolerant of homosexuals. Gay men are also often assumed to be hypersexual, animalistic, promiscuous, overly visible, and conspiratorial. Lesbians are assumed to be man haters, aggressive, socially nonconforming, and sexually cold (Herek, 1995). Until 1973, the American Psychiatric Association considered homosexuality to be a form of mental illness. Many people continue to hold this belief and also believe homosexuality to be immoral and antisocial.

Expressions of homophobia include verbal assaults and derisive joking, negative stereotypical media representations, discrimination in employment, education, housing, medical research, legal defense, and custody rights, physical attack, and tacit approval of all forms of discrimination, including gay bashing. One of the most widely publicized cases of homophobia-related violence is that of Matthew Shepherd, a college student in Laramie, Wyoming. One evening in 1998 two men offered Shepherd a ride home from a gay bar and then took him to a field where they beat and tortured him then tied him to a fence. He died a few days later. The case raised national awareness of gay-targeted beatings and murders.

Various studies, including surveys of gays and lesbians based on probability samples, indicate that nearly half of all respondents have experienced some form of discrimination in employment or housing based on their sexual orientation. The federal government has collected data on hate crimes since the 1990s. This information shows that, per capita, gays and lesbians report the greatest number of hate crimes and these crimes are more likely to be attacks on them personally, rather than attacks on property which are more common for other groups, such as African-Americans and Jews, who are also frequent targets of hate crimes (Rubenstein, 2003). Reports also show that gay men and transgender women prisoners are at greater risk of sexual assault than other prisoners while incarcerated (Jenness et al., 2011). In recent years, bullying of gender nonconforming students in schools has become a national issue. These students may or may not self-identify as gay, lesbian, or transgender, but their gender nonconformity is seen as deviant and punishable.

Institutional Heterosexism

Pervasive negative stereotypes regarding lesbians and gay men suggest that these attitudes and beliefs are rooted in cultural ideologies and social practices. All of these attitudes and expressions reflect the prevailing cultural belief that sexual desire for the opposite sex is expected and normal; sexual desire for someone of the same sex is abnormal and problematic. The lingering belief that homosexuality is dysfunctional and that it constitutes a state of anguish for the individual can be traced to the medicalization of homosexuality and its treatment as an illness. Many medical practitioners and clinicians continue to offer treatments intended to 'cure' lesbians and gays of their 'affliction'. These practices reflect the cultural belief that individuals will be unhappy and maladjusted if they do not experience sexual desire for persons of the opposite sex. Medical assessments that treat homosexuality as a form of disease reinscribe the notion that sexuality is primarily physiological and that heterosexuality is the healthy manifestation of human physiology.

Most contemporary religions also treat homosexuality as problematic. In some cases a distinction is made between homosexual feelings and homosexual acts (e.g., Catholic Catechism, 1989). The experience of homosexual inclinations may be considered an affliction – a 'cross to bear' – but to act on one's homosexual feelings is considered a sin. Many religious leaders advocate celibacy for those 'afflicted' with homosexual tendencies. Some religious organizations sponsor intensive therapy programs intended to help the individual who is 'suffering' from homosexuality to recover. Similar to medical institutions, religious institutions take heterosexuality for granted as the normal and desired form of sexual organization and treat homosexuality as deviant, undesirable, dysfunctional, and additionally, sinful.

Legal practices also reflect a cultural ideology that supports heterosexuality as normal and denigrates homosexuality as abnormal.

Containing Sexuality

Several theorists have observed that homophobia is an expression of a culture that is confused and inconsistent about sexual behavior. Attitudes and actions reflect both obsession with and repression of sexual desire. One basis of tacit agreement in the culture is that sexuality is something that must be contained. Homosexuality, along with adultery, prostitution, and pederasty, mark the boundaries by existing outside culturally approved forms of sexuality – what poet Rich (1980) refers to as compulsory heterosexuality. Social historians (e.g., Boswell, 1980; D'Emilio and Freedman, 1988; Katz, 1976) note that the emergence of a sexual binary in the nineteenth century posits heterosexuality as natural and socially desirable by contrasting it with homosexuality, which is characterized as unnatural and immoral. This binary represents the general tendency in modern Western thought to conflate morality and nature. According to this cultural equation, sexual desire is a manifestation of a natural drive to reproduce. The moral, disciplined individual contains this desire within the bounds of heterosexual monogamy. These attitudes are reflected in clinical, social, and religious definitions of the homosexual as cursed, perverted, sexually obsessed, and evil and, until recently, mentally and physically sick.

Internalized Homophobia

Though recent trends indicate that acceptance of gays is increasing for those in the urban middle class (Barrett and Pollack, 2005), homophobia and heterosexism are so culturally entrenched that many lesbians and gay men continue to live in a state of fear, and this is particularly true for minorities and those living in more culturally conservative regions. This entrenchment of heterosexist expectations and the corresponding active prejudice against homosexuality also induces feelings of 'internalized homophobia'. Internalized homophobia is a form of self-disgust and hatred experienced by many lesbians and gays. The phrase 'internalized homophobia' suggests that individuals who are trying to come to terms with their homosexual desires absorb or take in attitudes of cultural prejudice and use these attitudes as a basis of self-judgment. When the prevalent cultural story line is one of intolerance and debasement, then individual lesbians and gays are likely to have to deal with this in formulating their own sense of themselves.

In a culture that presumes heterosexuality, gays and lesbians must decide continually whether to make evident their deviant sexuality. 'Coming out' is an ongoing process. This process involves wrestling with and reconciling family, peer, and religious expectations with personal feelings and experiences. Many lesbians and gay men fear negative consequences for revealing their sexuality, and experience rejection or isolation by their families, friends, and religious and working communities when they reveal their homosexuality. Fear of rejection and a lack of positive role models can lead to confusion and self-hatred. Gay identified youth are one of the highest risk groups for suicide (Russell and Joyner, 2001). Recent studies compiled by the US Department of Health and Human Services and the University of California, Los Angeles (UCLA)-based Williams Institute indicate that lesbian and gay youth are up to five times more likely to attempt suicide than their heterosexual peers. More promising are the religious and community organizations that endeavor to understand and support gay and lesbian youth. These groups have been successful in reconciling family and social conflict and in integrating gay, lesbian, and transgender identified youth into their schools and communities.

Explanations for Homophobia/Heterosexism

Adam (1998) delineates three theoretical approaches to understanding homophobia. Each approach is distinguished by a conceptual term denoting a specific theoretical orientation to antihomosexual prejudice: Homophobia, Heteronormativity, and Heterosexism. Adam links these concepts to specific disciplines: psychology, cultural studies (literary), and sociology, respectively. The distinguishing aspect of each approach is the analytical unit: personality, discourse, and social structure. Explanations can be grouped accordingly.

Within the field of psychology, Herek (1995) defines the functional explanations that people hold and express because they derive psychological benefit from them. Herek proposes

three principle functions underlying attitudes about homosexuality: experiential, social identity, and ego defense. A person's attitude may be a consequence of personal experiences (positive or negative); a prejudiced attitude may be intended as an expression of identification with a particular social group; or it may be a defensive response to personal psychological conflicts (such as gender expectations). He emphasizes that it is important to recognize the nexus between these functional attitudes and cultural heterosexism. The source and expression of these attitudes directly reflects a person's perceptions of cultural expectations.

The development of literary cultural studies in the 1990s has generated several interrelated theories that come together under the term, 'queer theory'. Queer theorists (e.g., Butler, 1999; Sedgewick, 1990; Seidman, 1997) emphasize discursive practices that promote certain lines of thought and action, and discourage or punish others. Queer theorists stress that heteronormativity is one of the most prevalent discourses in contemporary Western culture, and focus on the manifestations of heterosexuality in art, media, education, legal discourse, religion, medicine, and so forth. According to these theorists, the dominant cultural discourse is saturated with images and ideals that promote heterosexuality and condemn homosexuality (or anything that does not fit the expected monogamous, heterosexual, family idea). Queer theorists have focused particularly on the experience of the 'closet' – physical and discursive practices intended to keep homosexuality hidden and contained in separate spheres.

Adam (1998) subsumes the psychological and cultural studies approaches within the sociological studies. His approach emphasizes social structure, particularly the ways in which psychological attitudes and the values revealed in cultural discourses are manifest and maintained through institutional structures and practices. Change, he suggests, will be a result not only of education against prejudiced attitudes and engaging in transgressive acts intended as critiques of taken-for-granted cultural practices, but will depend on the extent to which this education and alternative expression permeates and unsettles existing institutional arrangements (such as the family, law, and religion).

Gender Transgression

Understanding homophobia and heterosexism is rooted in the strong link between gender and sexuality in culture. Gender is the basic criterion by which we select sexual partners. The violation of expected gender behavior elicits taunting, prejudice, and physical and social abuse. Frequent targets of this prejudice include the mannish lesbian and the effeminate gay male. Both evoke stereotypes that represent violations of gender expectations and hint at sexual transgressions. Transgender persons are frequent targets of violence (*see* Transgender, Transexual, and Gender Variant Individuals). It is difficult to know if attackers of transgender persons are provoked by what they assume to be a sexual aberration or a gender violation. Given the tight connection between gender and sexuality, it is likely that any deviation is perceived as a threat to heterosexuality.

In the 1990s Lamba Legal Defense documented several cases in the US of murdered transgender persons in which the murderers were acquitted by the courts. The rationale offered in each case was that to arouse sexual desire in another under 'false gender pretense' was to invite violent 'self-defense' when the pretense was revealed (Singer and Deschamps, 1994). This rationale can be interpreted as a manifestation of homophobia; in effect the message is that individuals who do not conform to the expected norms of gender and sexuality do not deserve social justice.

Institutional Homophobia and Permissible Prejudice

The extent to which homophobia is institutionalized is indicated in the decisions of law enforcement officials, judges, politicians, and religious leaders who consider homosexuality sufficient grounds for justifying acts of prejudice, discrimination, and violence. This implicit approval constitutes a form of permissible prejudice. Persons presume their discriminatory attitudes are legitimate and permissible when these prejudices are supported by people in positions of authority.

The most prevalent indication of institutional homophobia is the widespread lack of legal protection from antigay/lesbian discrimination. Lesbians and gays who experience discrimination in employment, housing, education, and immigration often find it difficult to obtain justice. In some US states it is still legal to ban lesbians and gays from various public institutions. In 1993 a legal statute was implemented that prohibited harassment of closeted gay men and lesbians in the military, but also prohibited them from service if they were openly gay. This "don't ask don't tell" policy was overturned in 2011 (at a time when the US military was desperate to increase troops), but openly gay military personnel continue to report high rates of discrimination.

Another indication of institutional homophobia is public resistance to attempts by lesbians and gay men to reduce discrimination and to seek justice. In the 1990s US citizens in several states voted against ballot initiatives that would ensure equal legal protection for lesbians and gays in employment, housing, other public accommodations, or relationships. Opponents of nondiscrimination initiatives insisted that lesbians and gays were seeking 'special rights and privileges' The logic underlying this argument was that the US constitution already guarantees every individual equal protection under the law. This is true in theory, but advocates of the equality initiatives point out that in practice this protection is often not extended to lesbians and gays. In fact, many social officials, including employers, housing agencies, and health care providers actively refuse to grant lesbians and gays equal rights and openly cite deviant sexual orientation as the basis for this discrimination. US courts have routinely upheld these discriminatory actions.

Not only does the law fail to protect the rights of lesbians and gays, but it has been enforced differentially as a means of punishing lesbians and gays. One example of differential enforcement is the enactment of sodomy laws. Until recently, oral or anal sex was still prohibited in 14 states. Technically, these 'sodomy' laws refer to the behavior and not to the gender of the participants; anyone, straight or gay, can legally be punished for this behavior. However, the only recorded arrests in the past several decades based on these archaic laws have

been gays and lesbians. When challenged, several states (Kentucky, Louisiana, Michigan, and Texas) have ruled sodomy laws as unconstitutional. However, in 1986, in the case of Bowers v. Hardwick, the US Supreme Court upheld a Georgia sodomy law in a narrow vote of 5 to 4. The majority opinion, written by Chief Justice Warren Burger expresses the general legal failure to separate the expression of private individual sexual behaviors from perceived cultural expectations and focuses specifically on the gendered aspect of the behavior. In his brief he writes: "To uphold that *homosexual* sodomy is somehow protected as a fundamental right would be to cast aside millennia of moral teaching" (Bowers v. Hardwick, 1986, emphasis mine).

Court decisions such as Bowers v. Hardwick galvanized many US citizens who were concerned with the implications of court-mandated moral behavior and invasion of privacy. As a consequence, in the 1990s lesbians and gays fought actively against discrimination. Several gains were made, especially in areas such as housing and employment discrimination, but these efforts were matched in intensity by the rise antigay and antilesbian initiatives and legislation. The intent of initiatives such as Colorado's Amendment 2 (enacted in 1992 and overturned in 1996 by the Supreme Court in Romer v. Evans) was to officially prohibit lesbians and gays from seeking legal protection for discrimination based on their status as homosexuals. This preemptive legislation actively denied the pursuit of civil rights based on a single specific category – homosexuality. In an address to Congress regarding legislation intended to protect persons from discriminatory violence (hate crimes), Senator Dannemeyer makes clear this categorical prejudice. He notes: "(I)t is a Federal responsibility to ensure the equal protection of all citizens regardless of their race, religion, or ethnic origin. It is not a Federal obligation to protect citizens in their sexual orientation" (US Congress, 1988: p. 12).

Comments made by those with institutional authority such as Chief Justice Burger and Senator Dannemeyer buttress individual feelings of homophobia and send the message that discrimination and violence will be tolerated.

Social Movements

The social protests and political activism associated with lesbian and gay history can be interpreted as a response to widespread, organized manifestations of homophobia. Several observers have suggested that the struggle for gay and lesbian rights was *the* civil rights issue of the 1990s. This history represents a fight for rights that are constitutionally guaranteed to all US citizens but frequently withheld from gays, lesbians, bisexuals, and transgender people. Many local and national lesbian, gay, bisexual, and transgender movements have been organized as a direct response to political initiatives designed to legalize discrimination against homosexuals.

In the early 1990s various forms of antigay/lesbian legislation appeared on the ballots of 41 states and the District of Columbia. This sort of legislation is indicative of the extent to which homophobia is culturally legitimated as an institutionalized form of prejudice. Critics who suggest that antidiscrimination laws are 'special rights' fail to comprehend the extensive reach of homophobic actions into the everyday lives of lesbians, gays, bisexuals, and transgender persons. The Defense of Marriage Act introduced into US federal legislation in 1996 was one such case. The urgency with which several states have pursued legislation to restrict marriage to a man and a woman and to prohibit same-sex marriages is a display of mass homophobia.

Recent federal level acts as well as various social movements give the impression that institutional level homophobia is on the decline: In 2003 the Supreme Court overturned the state level sodomy laws in the decision of Lawrence v. Texas; In 2009 President Obama signed into law the Matthew Shepherd and James Byrd, Jr. Hate Crimes Act (Byrd was a young black man who was offered a ride and then beaten and dragged three miles to his death chained to the truck by three white men in Texas), the bill had lingered on the desk of the Bush administration for several years prior (Bush stated publicly that if passed in the House and Senate, he would veto the bill when it reached his office). Recently (2013) the US Supreme Court overturned Defense of Marriage Act (DOMA). This widely celebrated action provides federal recognition of the marriages of same gender partners who are legally married in states that allow same-sex marriage. The marriage equality movement and numerous antibullying campaigns (e.g., 'It Gets Better') have been central issues over the past decade. Many celebrities, religious leaders, and politicians courting votes have jumped on the bandwagon to support these particular causes.

Problematizing Homophobia

Is the tide turning on culturally sanctioned homophobia? A 2013 Pew Research study found that one in seven respondents had changed their minds from being opposed to same-sex marriage to support for it. Most people cited getting to know someone who was gay or lesbian and the reason for changing their minds. In the past decade, the presence of gay, lesbian, and transgender icons has risen in the media and, at least in some states, the public sentiment appears to be turning from extreme prejudice and discrimination to support for legal recognition and protection. To many observers, homophobia-based exclusion seems to be giving way to a new era of inclusion. How accurate is this perception and what does it imply for the future?

Many critics have challenged the progressive potential of both the marriage equality movement and the currently prolific representations of gays and lesbians in the media. They note that both the emphasis on marriage and the inclusion of gays and lesbians as ordinary, everyday people eclipses the full range of queer experiences. Feminist legal scholars (e.g., Polikoff, 2009) note that marriage has always been an exclusionary institution and predict that same-sex marriage will only serve reinforce traditional ideas of the 'good citizen' by punishing those who cannot or would not conform to traditional nuclear family ideals.

Homonormativity

In their 1997 book, *Homoeconomics*, Amy Gluckman and Betsy Reed describe the 'gay media marketing moment' as a period in the early 1990s in the US during which advertisers recognized that a certain class of people, namely urban gay white men,

were likely to have more discretionary income than the average married man. This recognition ushered in an era of direct marketing to gay men and lesbians and included imagery intended to reflect the interests and lifestyles of these potential consumers. This marketing focus probably did more for securing cultural citizenship for open and self-identified lesbians and gay men than any other form of political movement. In consumer-based capitalism, purchasing power is one of the hallmarks of citizenship. Representation in marketing campaigns is a manifestation of this 'cultural belonging'. One obvious implication of this form of cultural belonging is that it is limited to those who have the purchasing power.

Contemporary manifestations of 'gay chic' and related cultural expressions of acceptability regarding homosexuality (included in phrases such as 'queer in the streets, straight in the sheets', and 'metrosexual', etc.) reflect an increasing tolerance for homosexuality in certain regions of the world. Nonetheless, and again, ironically, although overt homophobia may be less allowable in some mainstream cultural venues, this so-called tolerance may come at a price. The price may be the increased exclusion and oppression of those who cannot or choose not to participate in these gay mainstreaming expressions. Furthermore, the ways in which this exclusion operates may be even more intractable and insidious than the forms of homophobia with which we are generally familiar (e.g., Bryant, 2008).

Historian Lisa Duggan refers to this trend as 'homonormativity' which is the proliferation of a culturally specific way of being gay that is enough in sync with existing gender, class, racial, and cultural norms as to be considered 'acceptable'. Expressions of homonormativity are the flip side of uncritically deployed homophobia. Together, both function to reinscribe culturally acceptable forms of gayness that render its associations with whiteness, gender appropriate behavior and (US influenced) middle-class status invisible and unproblematic.

Just as homophobia is a culturally learned prejudice, people learn to recognize the 'acceptable' homosexual based on cultural information – specifically portrayals in popular culture. What many people in Western countries, especially the US, think of when they consider homosexuality is the way in which it is portrayed in popular television shows and movies. The current era might be referred to as the post 'Will and Grace' or post 'L Word' or post 'Queer as Folk' era. In-depth analyses of these programs reveal an underlying set of rules about who and what is acceptable and these (homonormative) rules look very much like the rules for heteronormativity. This trend is reflected sloganistically in the shift away from the historically provocative call to action, "we're here, we're queer, get used to it," toward the more banal and assimilationist, "we're here, we're queer, let's go to Ikea."
